24 ABSTRACT

Aim: To validate an optimised Peptide-mediated magnetic separation (PMS)-Phage
 assay for detection of viable *Mycobacterium avium* subsp. *paratuberculosis* (MAP) in
 milk.

Methods and Results: Inclusivity, specificity and limit of detection 50% (LOD₅₀) of 28 the optimised PMS-phage assay were assessed. Plagues were obtained for all 43 29 MAP strains tested. Of 12 other Mycobacterium spp. tested, only M. bovis BCG 30 produced small numbers of plaques. LOD₅₀ of the PMS-phage assay was 0.93 MAP 31 32 cells per 50 ml milk, which was better than both PMS-qPCR and PMS-culture. When individual milks (n=146) and bulk tank milk (BTM, n=22) obtained from Johne's 33 affected herds were tested by the PMS-phage assay, viable MAP were detected in 34 35 31 (21.2%) of 146 individual milks and 13 (59.1%) of 22 BTM, with MAP numbers detected ranging from 6-948 PFU per 50 ml milk. PMS-qPCR and PMS-MGIT culture 36 proved to be less sensitive tests than the PMS-phage assay. 37

Conclusions: The optimised PMS-phage assay is the most sensitive and specific method available for the detection of viable MAP in milk. Further work is needed to streamline the PMS-phage assay, because the assay's multi-step format currently makes it unsuitable for adoption by the dairy industry as a screening test.

42 Significance and Impact of the study: The inclusivity (ability to detect all MAP 43 strains), specificity (ability to detect only MAP), and detection sensitivity (ability to 44 detect low numbers of MAP) of the optimised PMS-phage assay have been 45 comprehensively demonstrated for the first time.

46

47 Keywords: *Mycobacterium avium* subsp. *paratuberculosis* (MAP), PMS-phage
48 assay, detection sensitivity, detection specificity, milk testing

49 Introduction

50

Mycobacterium avium subsp. paratuberculosis (MAP) is the causative agent of 51 52 Johne's disease (JD), a chronic enteric wasting disease primarily affecting domestic ruminants (Stabel 1998; Sweeney 2011). Infected animals shed the pathogen in their 53 faeces and milk. JD is found throughout the world and many different estimates of 54 herd prevalence have been reported (Manning and Collins 2001; Tiwari et al. 2006; 55 Wilson et al. 2010). However, the true prevalence of JD among farmed animals is 56 57 unknown and, because of limitations of current methodologies for the detection of MAP, levels of MAP infection reported are likely to be underestimates in many 58 cases. A study carried out by Nielsen and Toft (2009) reviewed many prevalence 59 60 studies carried out across Europe and concluded that the prevalence of JD is likely to be >50% in many European countries. 61

There is some evidence to suggest an association between MAP and various 62 chronic long-term human disorders, including Crohn's disease (CD), irritable bowel 63 syndrome, Type 1 diabetes (T1DM), Multiple Sclerosis (MS), and more recently HIV 64 infection, sarcoidosis, and Hashimoto Thyroiditis (Waddel et al. 2015). Although the 65 role of MAP in the development, or progression, of any of these human diseases is 66 still unclear, recent meta-analysis studies demonstrated a significant association with 67 68 at least three of these human disorders including CD (Feller et al. 2007; Waddel et al. 2015; Timms et al. 2016), T1DM and MS (Waddel et al. 2015). Uncertainty about 69 the role of MAP as a human pathogen still remains, and there is general consensus 70 71 within the food safety community that human exposure to MAP should be minimized as a precautionary measure. Consumption of milk, and possibly meat, from infected 72 animals is currently viewed as a potential source of zoonotic transmission of the 73

pathogen from animals to humans. MAP has been isolated from retail milk and dairy
products in many parts of the world (Grant *et al.* 2002; Ayele *et al.* 2005; Ellingson *et al.* 2005; Carvalho *et al.* 2012; Paolicchi *et al.* 2012) suggesting that the pathogen
can enter the human food chain and that current High Temperature, Short Time
(HTST) pasteurization may not always ensure complete inactivation of this
pathogenic bacterium.

Traditional cultural methods cannot be routinely adopted to demonstrate the 80 presence of viable MAP in milk because the methods are time-consuming, not 81 specific and lack sensitivity (Slana et al. 2008a). Indeed, chemical decontamination 82 applied before culture to inactivate the competitive flora has been proven to have a 83 detrimental effect on the viability of MAP (Grant et al. 2003; Gao et al. 2005), and 84 85 also to extend the time required for primary isolation. A number of molecular tests including both conventional and quantitative PCR methods have been successfully 86 developed to permit faster detection of MAP in milk (Timms et al. 2011). However, 87 88 most of these tests do not provide information about the viability of detected cells and their sensitivity is generally affected by non-mycobacterial DNA, protein and 89 PCR inhibitors present in test samples, unless laborious DNA extraction methods are 90 applied before DNA amplification (Timms et al. 2015). 91

We recently combined an optimized phage amplification assay (Foddai *et al.* 2009) with selective peptide-mediated magnetic separation (PMS) (Foddai *et al.* 2010b) to achieve a rapid novel detection test for viable MAP. The PMS-phage method exploits the use of D29 mycobacteriophage and is able to provide rapid enumeration of viable MAP in milk and veterinary samples within 48 h (Foddai *et al.* 2011), based on the number of plaques (lysis areas) produced on a lawn of fastgrowing *M. smegmatis*. More recently, an optimized milk sample preparation protocol

to maximize accuracy of MAP counts when testing cows' milk was described (Foddai 99 and Grant 2015). The aims of the present study were: (1) to assess inclusivity and 100 specificity of the recently optimised PMS-phage assay by testing a large number of 101 102 MAP strains and other bacterial milk isolates; (2) to compare the limit of detection 50% (LOD₅₀) of the optimised PMS-phage assay with those of PMS-culture and 103 PMS-qPCR targeting both IS900 and f57 by testing artificially contaminated milk 104 samples; and (3) to test individual raw milk samples and bulk tank milk from dairy 105 herds affected by JD to assess the applicability of the optimised PMS-phage assay 106 107 for raw milk testing.

108

109 Materials and methods

110

111 Bacterial strains and growth conditions

Forty-three MAP strains (three type strains and 40 cattle, raw and pasteurised cow's 112 milk, untreated water, or Crohn's disease isolates, acquired or isolated over the past 113 20 years and available within the Queen's University Belfast (QUB) culture 114 collection), 12 other Mycobacterium spp. (Table 1), and five bacterial isolates (one 115 Gram positive coccus and four Gram positive rods) obtained by plating a sample of 116 raw cows' milk on Nutrient agar (Oxoid Ltd., Basingstoke, UK), were used in this 117 118 study. All MAP strains were grown in a shaker incubator for 4-6 weeks at 37°C to stationary phase in Middlebrook 7H9 broth containing 10% (v/v) OADC supplement 119 (both from Difco) and 2 µg per ml mycobactin J (Synbiotics Europe SAS, Lyon, 120 France). All Mycobacterium spp. were cultivated at appropriate temperatures 121 (dependent on species) to stationary phase (between 3 and 15 days) in the same 122

123 7H9 medium without the addition of mycobactin J. Milk isolates were grown 124 overnight in 10 ml of nutrient broth at 25°C.

125

126 **Peptide-mediated magnetic separation (PMS)**

PMS was performed on 1 ml of sample using 5 µL biotinylated-aMp3 peptide- and 5 127 µL biotinylated-aMptD peptide-coated MyOne[™] Tosylactivated Dynabeads® (Life 128 Technologies), prepared in-house as previously described (Foddai et al. 2010b). 129 Magnetic separation was carried out using the Dynal BeadRetriever (Life 130 131 Technologies). Magnetic capture was carried out for 30 min at room temperature under continuous mixing, followed by two washes in 1 ml Phosphate buffered saline 132 (PBS) containing 0.05% (v/v) Tween 20 (PBS-T20, Sigma), and final resuspension of 133 134 the beads in 1 ml 7H9 broth containing 10% (v/v) OADC.

135

136 **Optimised phage amplification assay**

The optimised phage assay was carried out as previously described by Foddai et al. 137 (2009). Briefly, after overnight incubation of samples at 37°C in 1 ml of 7H9 medium 138 containing 2 mmol I⁻¹ CaCl₂, samples were incubated for 2 hours at 37°C with 10⁸ 139 D29 mycobacteriophage before treatment with 100 mmol I⁻¹ ferrous ammonium 140 sulphate (FAS, Sigma) for 10 min at room temperature to inactivate any 141 exogenous/non-adsorbed seed phage. Samples were then mixed with 5 ml 7H9 142 medium containing 2 mmol I⁻¹ CaCl₂ and returned to the incubator at 37°C for a 143 further 90 min before being plated with tempered 7H9 agar and 1 ml Mycobacterium 144 smegmatis mc² 155 (10⁸ CFU per ml). Plaques were counted following overnight 145 incubation of plates at 37°C. 146

147

Confirmation of inclusivity of the novel PMS-phage assay by testing a broad range of MAP strains

Before being tested by the optimised PMS-phage assay, all stationary MAP broth 150 cultures were declumped by ultrasonication applied as previously described (Foddai 151 and Grant 2015) at 37 kHz for 4 min on ice in a Ultrasonic PH 30 (Fisher Scientific 152 Ltd) and then tested for purity (presence of only red acid-fast cells) by Ziehl-Neelsen 153 (ZN) staining. The number of cells per ml of broth was estimated by measuring the 154 optical density at 600nm (OD₆₀₀) using a WPA CO8000 cell density meter (SISLAB, 155 Italy). For each sample, optical density was adjusted to an OD₆₀₀ of 0.1 156 (approximately 10⁶-10⁷ MAP cells per ml) followed by serial dilution of cultures in 157 PBS-T20. PBS-T20 suspensions containing approximately 10²-10³ MAP per ml were 158 159 finally processed through optimised PMS-phage assay to assess inclusivity of the assay. The number of MAP cells detected was indicated by plaques (zones of 160 clearing) produced on agar plates containing 5 ml of molten 7H9 agar and 1 ml of M. 161 smegmatis mc² 155, and reported as plaque-forming-units (PFU) per ml. The 162 experiment was repeated twice for each of the 43 MAP strains. 163

164

Confirmation of specificity of the D29-based phage assay by testing various environmental *Mycobacterium* spp. and non-mycobacterial raw milk isolates

Broth suspensions of 12 environmental *Mycobacterium* spp. and five raw milk isolates spiked at three levels (10-10², 10²-10³, 10³-10⁴ cells per ml) were processed through the phage assay to assess specificity of the assay for MAP. For each sample tested, inoculum was prepared as described above. Number of bacterial cells per ml stationary phase broth was estimated by measuring and adjusting the

- original optical density followed by serial dilution of samples in 1 ml PBS-T20. The
 experiment was repeated twice for each *Mycobacterium* sp. and raw milk isolate.
- 174

Comparison of the limit of detection 50% (LOD₅₀) of the PMS-phage assay, PMS-culture and PMS-qPCR

Ultra-high temperature (UHT) milk purchased from a local supermarket and 177 artificially contaminated at different levels with MAP was used to compare the LOD₅₀ 178 of the three detection methods. Three sets of 50 ml UHT milk samples were spiked 179 in triplicate at four levels of MAP contamination (target final concentrations 10²-10³, 180 10-10², 1-10 and 0 PFU per 50 ml) by adding 1 ml of an appropriate dilution of MAP 181 NCTC 8578 or ATCC 19698 per 50 ml of milk. The number of MAP added at the 182 highest spiking level, in each case, was determined by the optimised phage 183 amplification assay (no PMS) applied to the diluted MAP culture used as inoculum. 184 Each set of 50 ml milk samples was processed through PMS followed by either the 185 phage amplification assay, culture or gPCR. Irrespective of detection method, milk 186 sample preparation included: (i) centrifugation at 2,500 x g for 15 min, (ii) declumping 187 by ultrasonication applied to the resuspended pellet fraction (Foddai and Grant, 188 2015), (iii) PMS, and then one of the following detection methods: 189

a) Phage assay applied after a previous overnight incubation of bead samples in 7H9 Middlebrook broth supplemented with 10% (v/v) OADC, 2 mmol l^{-1} CaCl₂ and NOA Antimicrobial Supplement (Product code 3A201N-300, Abtek Biological Ltd, Liverpool UK; final concentrations per ml of broth: Nystatin 50 IU, Oxacillin 2 µg, Aztreonam 30 µg);

b) Culture on plates of Herrold's egg yolk medium (HEYM) supplemented with 2 μg
 per ml mycobactin J and PANTA (Becton Dickinson; final concentrations per ml of

HEYM: 10 IU Polymyxin B, 1 µg Amphotericin, 4 µg Nalidixic acid, 1 µg Trimethoprim
and 1 µg Azlocillin);

c) qPCR targeting both IS900 and f57 (Donaghy *et al.* 2010) applied on MAP DNA
 released from captured cells through heating samples at 95°C for 25 min. All qPCR
 reactions were performed on an Eco[™] Real-Time PCR system (Illumina, Inc).

The limit of detection experiment was carried out with two MAP type strains, ATCC 19698 and NCTC 8578.

204

Testing of individual and bulk tank milks from Johne's affected herds

A total of 146 individual raw milk samples and three bulk tank milks (BTM) sourced 206 from a large JD affected dairy herd in southern England, identified with the help of Mr 207 Peter Orpin (Park Veterinary Group, Leicester), and 19 BTM obtained from dairy 208 herds in Scotland with the help of Dr George Caldow (SAC Consulting Services, St 209 Boswells) were tested for MAP. The individual milk samples were collected by farm 210 workers during one morning milking session into sterile 50 ml centrifuge tubes 211 supplied by QUB. Milk samples were immediately frozen and stored overnight on 212 farm before being transported to QUB in insulated boxes by an overnight courier. 213 Samples arrived at QUB in a partially frozen state and were immediately placed in -214 80°C freezer. Before application of the PMS-phage assay sample preparation 215 216 included: thawing overnight in the refrigerator at 4°C, room temperature for 1 h before centrifugation of 50 ml milk at 2500 x g for 15 min at room temperature, 217 resuspension of milk pellet fraction in 1 ml PBS-T20, application of ultrasonication to 218 219 disperse MAP clumps (Foddai and Grant 2015), and then PMS. After PMS, samples were concentrated in a final volume of 150 µl of sterile RNAse/DNAse free water 220 (Sigma) and divided into three aliquots (50 µl) to be processed via the three different 221

detection methods - phage amplification assay, culture, and real time qPCR asdescribed below.

224

225 Phage amplification assay and confirmatory Plaque PCR

Following overnight incubation of the bead samples at 37°C in a final volume of 1 ml 226 7H9 medium supplemented with 10% (v/v) OADC, 2 mmol I⁻¹ CaCl₂ and NOA 227 Antimicrobial Supplement (as described above), the phage amplification assay was 228 carried out as described by Foddai et al. (2009). After overnight incubation, plaques 229 (1 to, maximum, 10 depending on PFU counts) from positive phage assay plates 230 were harvested and processed through DNA extraction as described by Swift et al. 231 (2013). Plaque DNA in each aliquot was concentrated and purified through 232 233 Zymoclean[™] Gel DNA Recovery Kit (Zymo Research, Irvine, Ca, USA), and then subjected to IS900 Plaque-PCR as described by Stanley et al. (2007). 234

235

236 Culture and confirmation of MAP isolation

After PMS, samples were cultivated in BD BBL MGIT[™] Mycobacteria Growth 237 Indicator Tubes containing 4 ml of modified Middlebrook liquid broth enriched with 238 0.5 ml BBL[™] MGIT[™] OADC and 0.1 ml MGIT[™] PANTA[™] antibiotic mixture (all 239 Becton Dickinson Limited, USA). Cultures were incubated for 16-20 weeks at 37°C 240 and were periodically monitored using a BACTEC MicroMGIT reader (Becton 241 Dickinson Limited, USA). Liquid broths showing evidence of growth were tested by 242 ZN staining for the presence acid-fast bacilli and by IS900 PCR (Naser et al. 2013) 243 to identify MAP positive cultures. All cultures that tested acid-fast and IS900 PCR 244 positive were then subjected to a mild chemical decontamination treatment in 0.75% 245 (w/v) hexadecylpyridinium chloride (HPC) for 60 min at room temperature before 246

being sub-cultured onto Herrold's egg yolk agar (HEYM) slopes supplemented with
mycobactin J and PANTA. Slopes were incubated at 37°C for over 10 months to
achieve isolation of typical colonies and final identification as MAP.

250

251 Real time qPCR

Each sample analysed by real time gPCR targeting IS900 and f57 MAP sequences 252 (Donaghy et al. 2010) was tested in duplicate. DNA was released from PMS samples 253 by heating samples at 95°C for 25 min. After brief centrifugation at 10,000 g for 1 min 254 255 to sediment beads, an aliquot of 2.5 µl of the supernatant was used per qPCR reaction. Each gPCR reaction was performed in a final volume of 25 µl including: 256 TaqMan Universal 2X PCR master mix (Applied Biosystems), EXO IPC 10x mix and 257 258 EXO IPC 10x DNA (Applied Biosystems), 10 µmol I⁻¹ of each forward and reverse primer, 5 µmol I⁻¹ of specific probe (Donaghy et al. 2010), and 2.5 µl template DNA. 259 PCR was performed using an Eco[™] Real-Time PCR system (Illumina, Inc) with the 260 following thermal cycling conditions: 50°C for 2 min; 95°C for 10 min, and 40 cycles 261 of 95°C for 15 s and 60°C for 1 min. 262

263

264 Statistical analysis of results

For inclusivity and specificity testing, positive or negative results for the plaque assay applied after PMS were used as a final result. Limit of detection (LOD₅₀) and associated 95% confidence limits of the three methods assays (PMS-phage assay, PMS-culture, PMS-IS900 and f57 qPCR) were estimated using the generalized Spearman-Karber LOD₅₀ calculation for 4-level spiking protocols (AOAC International 2006). Kappa agreement between test results was determined using EpiTools Epidemiological Calculators (<u>http://epitools.ausvet.com.au</u>).

272

273 **Results**

274

275 Confirmation of inclusivity of the novel PMS-phage assay

All 43 MAP strains tested by the PMS-phage assay yielded plaques, confirming 100% inclusivity of the test (Figure 1). PFU counts observed for most of the MAP strains (40 of 43, 93%) ranged from 100 to 300 (mean 142.26±51.97 PFU per ml); the number of plaques expected based on the culture dilution tested. Three MAP strains (NCTC 8578, 307R and Van Veen 52991-1) showed greater variability in counts between replicates and a higher mean PFU ml⁻¹ count (mean 681.50±165.91 PFU per ml) than was observed for the other strains tested (Figure 1).

283

284 Confirmation of specificity of the PMS-phage assay

Eleven of the 12 non-target *Mycobacterium* spp. tested negative by the PMS-phage assay (i.e. no plaques observed), as did all five raw milk bacterial isolates tested. Some plaques were observed for *M. bovis* BCG at the highest spiking level $(10^3-10^4$ CFU per ml) tested only, however the number of plaques (6.5 and 10.5 PFU per ml) after PMS was substantially lower than the original spiked population (data not shown). The mean percentage non-specific recovery of *M. bovis* BCG observed in two separate experiments was $0.19\pm0.08\%$.

292

293 Comparison of the LOD₅₀ of the PMS-phage assay, PMS-culture and PMS-294 gPCR

295 Before testing by the three methods, spiked UHT milk samples contained 920, 92 296 and 9 PFU per 50 ml of MAP ATCC 19698, and 860, 86 and 8 PFU per 50 ml milk of

MAP NCTC 8578; determined by the optimised phage amplification assay (without 297 PMS). Higher detection sensitivity for MAP was exhibited by the PMS-phage assay 298 compared to the PMS-qPCR and PMS-culture assays applied in parallel to spiked 299 300 milk samples. The LOD₅₀ of the PMS-phage assay was estimated to be 0.90 and 0.95 PFU per 50 ml milk (calculation of 95% CI not possible) for MAP strains NCTC 301 8578 and ATCC 19698, respectively (Table 2). PMS-IS900 gPCR had the next 302 highest detection sensitivity, followed by PMS-f57 gPCR, and finally PMS- culture. 303 The LOD₅₀ of PMS-IS900 qPCR was 136.7 (95% CI: 21.4-872.9) and 134.55 (95% 304 305 CI: 23.45-772.80) MAP cells per 50 ml milk for strains NCTC 8578 and ATCC 19698, respectively; the LOD₅₀ of f57 qPCR was 303.7 and 291.00 MAP cells per 50 ml milk 306 (calculaton of 95% CI not possible) for strains NCTC 8578 and MAP ATCC19698, 307 308 respectively (Table 2). An LOD₅₀ for PMS-culture could not be calculated because none of the milk samples spiked at the highest level (10²-10³ CFU per 50 ml) yielded 309 colonies on HEYM agar plates, and thus use of the Excel LOD₅₀ calculator (AOAC 310 311 International, 2006) was not valid.

312

313 Testing of individual and bulk tank milks from Johne's affected herds

Table 3 summarises the number and percentage of individual and bulk tank milk 314 samples testing MAP positive by the three detection methods. Overall, 59 milk 315 316 samples yielded plaques in the PMS-phage assay, some or all of which (depending on numbers present) were harvested and subjected to IS900 Plague-PCR. Of the 317 59 plaque composites tested by IS900 Plaque-PCR, 44 (31 from individual milks and 318 13 from BTM, 74.6%) yielded clear, positive IS900 Plaque-PCR results, 5 (8.5%) 319 yielded inconclusive PCR results, 10 (16.9%) yielded negative PCR results, and one 320 was not tested because plaques had merged and individual plaques could not be 321

harvested. Therefore, viable MAP were confirmed to be present in 31 (21.2 %) of 146 individual milks and 13 (59.1%) of 22 BTM tested by the PMS-phage assay (Table 3). Mean viable MAP counts indicated by the PMS-phage assay in the positive individual raw milks and bulk tank milks were 228.1 PFU per 50 ml (range 6-948 PFU per 50 ml) and 136.83 PFU per 50 ml (range 18-685 PFU per 50 ml), respectively.

Due to budget restrictions, and the relatively high cost of qPCR testing, real 328 time qPCR was only used to test all 22 bulk tank milks and selected individual raw 329 330 milk samples (n=77, 47 samples that had tested PMS-phage assay positive and 30 other randomly selected samples that had tested PMS-phage assay negative). This 331 may have biased the outcome of the PMS-qPCR tests, so direct comparisons with 332 333 the outcomes of the PMS-phage assay and PMS-culture will not be made. MAP was detected by qPCR in 7 (9.1%) out of 77 individual raw milk samples and 10 (45.4%) 334 out of 22 BTM tested. IS900 qPCR showed higher detection rates than f57 qPCR, as 335 expected. Of the seven individual raw milks that tested qPCR positive, all 7 (9.1%) 336 tested IS900 qPCR positive and 2 samples (2.6%) tested both IS900 and f57 qPCR 337 positive. Of the 10 BTM that tested qPCR positive, 10 (45.4%) tested IS900 qPCR 338 positive, only 2 (9.1%) tested both IS900 and f57 qPCR positive. 339

When cultured in MGIT broth (not HEYM agar plates, as in first part of the study) after PMS, 49 (33.6%) of the 146 individual raw milk cultures and 16 (72.7%) of the 22 BTM cultures showed evidence of acid-fast bacteria when tested by ZN staining; many of these cultures were mixed cultures and showed evidence of the presence of non-acid-fast bacteria. Isolation of MAP cells was confirmed in 17 (11.6%) individual raw milk and 11 (50%) BTM cultures by IS900 PCR (Naser *et al.* 2013). Inter-relationships between results of the PMS-phage assay, PMS-culture

and PMS-qPCR applied to individual raw milks and BTM are shown as Venn 347 diagrams in Figure 2. It should be noted in the case of the individual raw milks, 9 of 348 the 17 milk samples that tested PMS-culture positive (Figure 2A) and 2 of the 7 milk 349 samples that tested PMS-qPCR positive (Figure 2B) also yielded plaques with the 350 PMS-phage assay; however the presence of MAP DNA in the plaques harvested 351 was either not confirmed by Plague-PCR or the plague-PCR result was inconclusive, 352 and so a PMS-phage assay negative result was recorded. Two BTM samples tested 353 PMS-phage assay negative but PMS-culture, and PMS-culture and qPCR positive 354 355 (Figure 2C). It is possible that overgrowth of environmental mycobacteria adhering to the peptide-coated magnetic beads going into the phage assay may have masked 356 plaques in the *M. smegmatis* lawns for these samples. As no plaques were 357 358 observed, these two samples were recorded as PMS-phage assay negative as a result, when potentially this was a false negative result. 359

Overall, agreement between results of the PMS-phage assay and those of PMS-culture and PMS-qPCR tests was 'fair ' and "poor", respectively, when 146 individual milks were tested (PMS-phage v PMS-culture: Kappa 0.25, 95% CI: 0.062 to 0.439, P=0.0028; PMS-phage v PMS-IS900 qPCR: Kappa 0.073, 95% CI: -0.084 to 0.231, P=0.1695), whereas it was 'moderate' in both cases when 22 BTMs were tested (PMS-phage v PMS-culture: Kappa 0.538, 95% CI: 0.184 to 0.892, P=0.0056; PMS-phage v PMS-IS900 qPCR: Kappa 0.553, 95% CI: 0.220 to 0.885, P=0.0036).

367

368 **Discussion**

369 Culture is still generally considered the 'gold standard' method to demonstrate the 370 presence of viable MAP in test samples. However, the method is time consuming, 371 takes weeks to yield results, and any MAP counts obtained are going to be

underestimates due to the inclusion of a chemical decontamination step prior to 372 culture which can adversely impact MAP viability. There is interest amongst dairy 373 producers and processors to identify a rapid method that could be adopted to detect 374 the presence of MAP in raw milk from primary suppliers and dairy products produced 375 from this milk. The aim of this study was to evaluate the performance of an already 376 described PMS-phage assay (Foddai et al. 2011) for the rapid detection of viable 377 MAP in cows' milk that has undergone further optimisation over recent years (Foddai 378 and Grant, 2015). The method exploits the ability of D29 mycobacteriophage to 379 replicate and amplify within only viable mycobacterial cells and represents an 380 optimized version (Foddai et al. 2009; Foddai et al. 2010a) of the commercially 381 phage-based test (*FASTPlaque*TB[™] assay, Biotec Laboratories Limited, Ipswich), 382 383 which was originally developed for the rapid detection of viable *M. tuberculosis*. In order to maximize specificity of detection, the phage amplification assay is applied 384 after selective capture of MAP cells on paramagnetic beads coated with two 385 selective anti-MAP peptide binders (Foddai et al. 2010b). To date, only results of 386 PMS-phage assay testing of a limited number of naturally contaminated BTM (n=44) 387 and faeces (n=39) samples have been reported, providing proof-of-concept for the 388 PMS-phage assay (Foddai et al. 2011). Further refinements to the milk testing 389 procedure, mostly related to optimising milk sample preparation prior to PMS, have 390 391 been made since 2011. Therefore, this study was carried out to assess inclusivity, specificity and detection sensitivity of an optimised version of the PMS-phage assay, 392 and to compare this assay with PMS-culture and PMS-qPCR. 393

Inclusivity of a microbiological test is the ability to detect the target microorganism within a wide range of bacterial strains. Prior to this study a limited range of MAP strains had been tested by PMS and also by the phage amplification

397 assay (Foddai et al. 2009; Foddai et al. 2010a, 2010b). A much broader range of MAP strains (n= 43) isolated from various sources (animals, milk, water and 398 humans) was tested as part of this study to demonstrate inclusivity for MAP of the 399 400 two peptide binders aMp3 and aMptD involved in the PMS, and of the D29 mycobacteriophage involved in the phage amplification assay. The observation of 401 plaques when the MAP strains were tested demonstrated that all strains were 402 successfully infected by D29 mycobacteriophage, and this finding confirmed 100% 403 inclusivity for MAP. Although some variability in PFU counts was observed, similar 404 405 plaque counts were observed for the vast majority (93%) of MAP strains tested. This also suggests that consistent capture was being achieved by the two peptide binders 406 during PMS. Due to the hydrophobic nature of its cell wall, MAP cells tend to 407 408 aggregate in clumps, the presence of which impacts accurate enumeration of viable MAP cells in tested samples. The appearance of the MAP broths before testing 409 visibly differed between strains, likely due to variations in clump size and distribution, 410 411 and even after de-clumping some broths still showed visible clumps that had not been fully dispersed. These observations might explain the variability in PFU counts 412 observed for different MAP cultures, and lower PFU counts may have resulted due to 413 counting of clumps of cells rather than just single cells. Conversely, MAP cultures 414 that contained larger clumps that were effectively dispersed into single cells by 415 416 ultrasonication treatment would yield higher PFU counts; which was apparently the case for MAP strains NCTC 8578, 307R and Van Veen 52991-1. In the case of MAP 417 strains showing particularly large standard deviations in Figure 1, the efficiency of 418 the de-clumping step has clearly differed more between the duplicate MAP 419 suspensions tested for these strains compared to the other MAP strains tested. The 420 latter finding suggests that different degrees of de-clumping were being achieved by 421

the ultrasonication treatment applied before PMS; thus ultrasonication conditions forMAP de-clumping purposes may need further optimization.

In relation to specificity, this study assessed if the D29 mycobacteriophage 424 involved in the phage assay was capable of infecting other *Mycobacterium* spp., or 425 other raw milk bacteria, which might potentially lead to formation of plaques in the 426 absence of MAP when the method is used to test milk samples. A previous study 427 carried out by Rybniker et al. (2006) reported that the D29 mycobacteriophage can 428 infect various Mycobacterium spp. including M. smegmatis, M. tuberculosis, M. bovis 429 BCG, M. avium, M. scrofulaceum and M. ulcerans, whereas it was unable to infect 430 M. marinum, M. fortuitum and M. chelonae. The assay used in this study was 431 modified for MAP based on its specific burst time, which was found to be longer than 432 433 for other Mycobacterium spp. (Foddai et al. 2009). As cell lysis is dependent on the host's generation time, the D29 phage requires a longer time (220 min) within MAP 434 cells to replicate and release the new phage progeny than in other faster-growing 435 436 Mycobacterium spp.; the burst time of which generally ranges between 1 and 2 hours (David et al. 1980). Consequently, the virucidal treatment applied after two 437 hours of incubation with D29 bacteriophage would have no detrimental effect against 438 phage particles still to be released from MAP cells, whereas it inactivates any 439 progeny phage already released from faster-growing mycobacteria. This explains the 440 441 absence of plaques for almost all Mycobacterium spp. tested in this study. Some plaques were only observed with *M. bovis* BCG, which is the sole *Mycobacterium* sp. 442 tested with a similar burst time to MAP (180 min; Foddai and Grant unpublished 443 data). However, minimal recovery of *M. bovis* BCG (<1%) was observed when the 444 test was applied after PMS, confirming the high specificity (>99%) of the test for MAP 445 if the optimized phage assay is applied in combination with PMS. Finally, no plaques 446

were observed for any of the milk bacteria tested, suggesting no risk of interferencefrom bacterial species that might be encountered when testing raw milk for MAP.

Detection sensitivity, specifically LOD₅₀, was the last aspect of the PMS-449 phage assay investigated in the present study. Evidence to date suggests that MAP 450 is typically present in raw milk in low numbers (Sweeney et al. 1992; Slana et al. 451 2009). Since conventional culture often does not have sufficient sensitivity (Slana et 452 al. 2008a), an alternative detection method is required to rapidly demonstrate the 453 presence of viable MAP in milk and achieve more accurate enumeration. Results 454 455 from testing of both artificially and naturally infected milk samples indicate that the optimised PMS-phage assay possesses the sensitivity needed to detect low levels of 456 MAP in raw milk. The optimised PMS-phage assay demonstrated higher sensitivity 457 458 than both PMS-culture (on HEYM agar plates) and PMS-qPCR, targeting either IS900 or f57, when the test was used to test whole milk spiked at different levels with 459 two MAP strains. Plaques were observed from all the milk samples, including those 460 originally spiked with 1-10 MAP cells per 50 ml. Higher LOD₅₀ were observed for the 461 two other PMS-based detection methods (≥ 100 PFU per 50 ml). The higher MAP 462 detection rates observed with the PMS-phage assay during raw milk testing further 463 confirmed the higher sensitivity of this test compared to PMS-culture and PMS-464 qPCR. Viable MAP cells were detected by PMS-phage assay in 21.2% of individual 465 466 milk samples and 59.1% of BTM samples tested. These detection rates were consistently higher than corresponding rates observed for PMS-IS900 gPCR (9.1% 467 and 45.4%, respectively), PMS-f57qPCR (2.6% and 9.1%, respectively) and PMS-468 culture (11.6% and 50%, respectively). It should be noted that for raw milk testing 469 MGIT broth was employed rather than HEYM agar plates for culture after PMS, and 470 it was noticeable that the detection sensitivity of PMS-culture was much improved, 471

472 compared to the outcomes of LOD₅₀ determinations using spiked milk. From past
473 experience, liquid culture does tend to be more conducive for MAP growth than solid
474 culture. The optimised PMS-phage assay proved to be a more sensitive and quicker
475 alternative to conventional culture for demonstrating the presence of viable MAP in
476 cows' milk.

Application of the optimised PMS-phage assay to test naturally infected milks 477 during this study provided new information on numbers of viable MAP present in milk 478 from individual animals and BTM from Johne's affected herds. Mean MAP counts 479 estimated from individual infected cows and BTM milk were 228 PFU per 50 ml 480 (range 6-948 PFU per 50 ml) and 144.9 PFU per 50 ml (range 18-685 PFU per 50 481 ml), respectively. These PMS-phage assay counts are higher than previous 482 483 estimates of the numbers of MAP cells in both individual milk samples (2 to 8 CFU per 50 ml, Sweeney et al. 1992; <100 CFU per ml, Giese and Ahrens 2000; 4 to 20 484 CFU per 50 ml, Ayele et al. 2005; 10 to 560 cells per ml, Slana et al. 2008b) and 485 BTM (1 to 9 cells per ml, Slana et al. 2008b and "several tens of cells per ml", Slana 486 et al. 2009), which were obtained by either culture after chemical decontamination or 487 real-time qPCR. 488

On the basis of the inclusivity, specificity, and sensitivity of the PMS-phage 489 assay reported here, and its superior performance relative to PMS-gPCR and PMS-490 491 culture for testing raw milk samples, the PMS-phage assay represents the most sensitive test available to detect viable MAP in milk. However, as currently 492 performed, the PMS-phage assay involves two overnight incubations, multiple timed 493 steps and additions of reagents, and a plaque PCR to confirm MAP detection; so is 494 laborious to carry out and it takes 2-3 days to obtain a MAP positive result. Only with 495 considerable practice in application of the PMS-phage assay over several years 496

have consistent results been obtained within our laboratory. Whilst the phage amplification assay and PMS-phage assay are proving to be valuable MAP research tools, the PMS-phage assay is not suitable for adoption by the dairy industry as a milk screening test in its current format. The assay would require some streamlining, specifically to eliminate the need for the plaque assay and plaque PCR after phage amplification, in order to potentially become such a test. Potential avenues to achieve this goal are currently being explored in our laboratory.

To conclude, this study has demonstrated that the optimised PMS-phage 504 505 assay is 100% inclusive for all MAP strains tested, >99% specific for MAP, and has a LOD₅₀ of ~1 PFU per 50 ml milk. When used in combination with the optimized milk 506 sample preparation protocol (Foddai and Grant, 2015), the assay detected viable 507 508 MAP in raw milk from a substantial proportion (21.2%) of individual cows in a JD affected dairy herd (mean MAP count 228.1 PFU per 50 ml) and in 59.1% of BTM 509 from JD affected dairy farms in Scotland (mean MAP count 136.83 PFU per 50 ml). 510 This study has also demonstrated that the optimised PMS-phage assay is more 511 sensitive than both PMS-qPCR and PMS-culture (on HEYM or in MGIT liquid 512 medium). Unfortunately, in its present multi-step format, the PMS-phage assay does 513 not represent a test that could be easily adopted by the dairy industry for routinely 514 screening large numbers of milk samples to detect the presence of MAP. Efforts are 515 continuing to streamline the assay, whilst maintaining its excellent detection 516 sensitivity, to make it suitable for that purpose. 517

* Only reported PMS-phage assay positive when DNA harvested from plaques tested Plaque-PCR positive.

⁶⁶⁵ ⁺ Only reported PMS-culture positive if presence of MAP confirmed by IS900 PCR applied to broth culture.

⁶⁶⁶ ‡ All 146 individual milk samples were not tested by either PMS-qPCR assay due to cost constraints. The 77 samples tested

included 47 samples that had yielded plaques with the PMS-phage assay plus 30 other randomly selected PMS-phage assay
 negative samples.

Figure 1. Inclusivity of the optimised PMS-phage assay demonstrated by testing 43
different MAP strains, and variation in plaque counts obtained for duplicate tests on
each strain. Data represent mean plaque count +/- standard deviation.

Figure 2. Venn diagrams showing inter-relationships between optimised PMS-phage assay, PMS-culture and PMS-IS900 qPCR results for individual raw milk samples (A and B) and BTM samples (C). An asterisk indicates that the corresponding PMSphage assay yielded plaques but presence of MAP DNA was not confirmed by plaque-PCR, and so PMS-phage assay result was recorded as negative.
