Abstract

We perform non-LTE inversions in a large set of umbral flashes, including the dark fibrils visible within them, and in the quiescent umbra by using the inversion code NICOLE on a set of full Stokes high-resolution Ca II $\lambda 8542$ observations of a sunspot at disk center. We find that the dark structures have Stokes profiles that are distinct from those of the quiescent and flashed regions. They are best reproduced by atmospheres that are more similar to the flashed atmosphere in terms of velocities, even if with reduced amplitudes. We also find two sets of solutions that finely fit the flashed profiles: a set that is upflowing, featuring a transition region that is deeper than in the quiescent case and preceded by a slight dip in temperature, and a second solution with a hotter atmosphere in the chromosphere but featuring downflows close to the speed of sound at such heights. Such downflows may be related, or even dependent, on the presence of coronal loops, rooted in the umbra of sunspots, as is the case in the region analyzed. Similar loops have been recently observed to have supersonic downflows in the transition region and are consistent with the earlier “sunspot plumes,” which were invariably found to display strong downflows in sunspots. Finally, we find, on average, a magnetic field reduction in the flashed areas, suggesting that the shock pressure is moving field lines in the upper layers.

Key words: Sun: activity – Sun: atmosphere – Sun: chromosphere – Sun: transition region – sunspots

1. Introduction

Present-day inversion codes like SIR (Ruiz Cobo & del Toro Iniesta 1992), SPINOR (Frutiger et al. 2000; van Noort 2012), STIC (de la Cruz Rodríguez et al. 2016), and NICOLE (Socas-Navarro et al. 2015) allow us to compute semiempirical model atmospheres in the millions per data set, covering a wide range of dynamically evolving structures. High-resolution data allow the study of small-scale variations, in space and time, of highly dynamic fine-structured events such as umbral flashes, as well as providing new insights into earlier modeling work where dynamic phenomena tend to be averaged together.

Umbral flashes were first characterized by Beckers & Tallant (1969) in the Ca II H and K lines, who proposed that these are acoustic shocks based on their propagation across field lines, with such propagation confirmed that same year by Wittmann (1969). They display a shock-characteristic sawtooth pattern, known as “z-pattern” in early literature (Thomas 1984). These seem to steepen directly from the photospheric 3-minute oscillations (Thomas 1985; Centeno et al. 2006). With an atmospheric model that included a forced piston, Bard & Carlsson (2010) apply 1D non-LTE (NLTE) radiative transfer using MULTI (Carlsson 1986), to successfully reproduce the flash intensity profiles in Ca II H, as well as the sawtooth pattern. The latter can have peak-to-peak velocities of up to 15 km s^{-1} (Roupe van der Voort et al. 2003; Tian et al. 2014), as observed also in Ca II H. This pattern is also observed in He I, with peak-to-peak amplitudes of up to 11 km s^{-1} (Lites 1986). Further up, umbral flashes seem to be precursors to the running waves observed in the transition region (Madsen et al. 2015; Löhner-Böttcher 2016). Latency between different chromospheric lines indicates upward-propagating waves and energy, but the estimates of the mechanical energy do not seem

sufficient to compensate for the radiative losses (Kneer et al. 1981). For a recent review of the properties of umbral flashes in a broader context (such as their connection to running penumbral waves), see Jess et al. (2015) and Khomenko & Collados (2015).

Early umbra semiempirical models featuring a chromosphere include Maltby et al. (1986) and more recent automated inversion work such as Beck et al. (2013) and Westendorp Plaza et al. (1997), who used the SIR code (Ruiz Cobo & del Toro Iniesta 1992) in the Ca II H line and the 6302 line pair, respectively. Both include magnetic field values for the umbra of sunspots above 2000 G in the chromosphere, indicating little change in the magnetic flux from the photosphere to the chromosphere. This agrees with the observations of Westendorp Plaza et al. (1997), who find only a small reduction of the magnetic field strength, 2400–2100 G, at $\log \tau_{500} = -2.8$, for an umbral average of the inverted data. For a more comprehensive review of earlier umbral models, please refer to Solanki (2003). However, the chromosphere in these models was either extrapolated or directly inferred from LTE modeling.

The first spatially continuous 3D model of a sunspot, produced using NLTE inversions in a chromospheric line, was that of de la Cruz Rodríguez et al. (2013), who found enhancements of up to 1000 K in the flashed atmosphere and a magnetic field oscillation, modulated by the flashes, using the weak-field approximation. Inversions in the chromosphere tend to yield highly inhomogeneous results, both vertically and spatially (Pietarila et al. 2007), which presents challenges to interpretation. For a recent review on the state of the art of inversions, see de la Cruz Rodríguez & van Noort (2016).

Socas-Navarro et al. (2000a) found abnormal Stokes profiles in the flashed phase itself that hinted at unresolved features. Socas-Navarro et al. (2000b, 2001) successfully fitted (in

NLTE) flashed and quiescent profiles with a linear combination of a two-component (unresolved) atmosphere, one upflowing and the other gently downflowing, where the proportion of each component would vary in time to reproduce the observed profile variation. In the infrared, Centeno et al. (2005) studied time series of flashes and found evidence for two components both in a temporal and in a spatial sense, which was interpreted as evidence for separate channels for upflows and downflows. Nagashima et al. (2007) found a node-like feature over the dark umbra where power was suppressed at 5.5 mHz power maps as seen in Ca II H. Also in Ca II H, Socas-Navarro et al. (2009) found dark fibrils in high-resolution *Hinode* filtergrams, with longitudinal horizontal projections as long as 2000 km. This observation was confirmed in a different sunspot by Henriques & Kiselman (2013). Henriques et al. (2015) found that such streaks could be even longer and stable for at least two flashes, with evidence for the presence of the same fibrils over more than three flashes. Two populations of features seemed to exist, with the longest observed feature extending over the penumbra and showing signs of a change of inclination when crossing the umbra–penumbra boundary, and the smaller fibrils having a partial match with H α features, with properties consistent with short dynamic fibrils. The latter is in agreement, at least partially, with the work where short dynamic fibrils were discovered (Roupe van der Voort & de la Cruz Rodríguez 2013) and in agreement with the likely identical H α spikes (Yurchyshyn et al. 2014). Why such dark fibrils, as well as the likely related short dynamic fibrils, are visible at all is still an open question, due to an absence of an identified source of inhomogeneities in the chromosphere of the umbra of sunspots. Other umbral fine structure, umbral microjets, have been observed in emission in Ca II H by Bharti et al. (2013) and likely have a nondirect relation with short dynamic fibrils (Nelson et al. 2017).

In this work we have produced and analyzed an array of umbral models that reproduce the observed time series of Stokes profiles. Limited attention is given to any one single fit, and we make use of the large amount of atmospheres, generated by the inversion procedure, to gain insight into the above phenomena and the possible source of inhomogeneities in the umbra.

2. Observations and Data Processing

We used the CRisp Imaging Spectropolarimeter (CRISP; Scharmer 2006; Scharmer et al. 2008) instrument, at the Swedish 1 m Solar Telescope (SST; Scharmer et al. 2003a). Adaptive optics were used, including an 85-electrode deformable mirror that is an upgrade of the system described in Scharmer et al. (2003b). All data were reconstructed with Multi-Object Multi-Frame Blind Deconvolution (MOMFBD; Löfdahl 2002; van Noort et al. 2005), using 82 Karhunen–Loève modes sorted by order of atmospheric significance and 88×88 pixel subfields.

A prototype of the data reduction pipeline published by de la Cruz Rodríguez et al. (2015b) was used before and after MOMFBD. This includes the method described by Henriques (2012) for consistency between the different liquid crystal (LC) states and wavelengths, with destretching performed as in Shine et al. (1994).

The observations were normalized to the intensity of the continuum levels by fitting the FTS atlas profile (Neckel 1999),

convolved with the CRISP wavelength profile, to an average of the quiet-Sun profile computed from multiple scans (averaging over every fifth scan). The main target of the observations and of the inversions was the largest umbra of the main sunspot in the NOAA 12121 active region, when it was close to disk center ($x = 76''$, $y = 46''$), between 10:43 and 11:23 UT on 2014 July 28. Figure 1 shows the inverted field of view (FOV).

The spatial sampling is $0''.0592$ per pixel, with the spatial resolution reaching up to $0''.18$ over the FOV of 41×41 Mm. The Ca II $\lambda 8542$ line was sampled from -290 to $+290$ mÅ in steps of 73 mÅ (as measured from the averaged observed core of the line in a quiet area at disk center) and at -942 , -580 , -398 , $+398$, $+580$, and $+942$ mÅ, for a total of 15 wavelengths. The observed line positions can be seen as plus signs in Figure 2. Full Stokes polarimetry was achieved by using four LC states and a demodulation scheme that included a calibration of the optics on table from the telescope primary focus to the science focus, taken less than 3 hr from the observations, and a telescope model spanning the primary focus up to and including the primary lens. The latter was produced from calibrations taken the same year and includes daily variations of the telescope modulation (see Schnerr et al. 2011; de la Cruz Rodríguez et al. 2015b). Our inversions overestimated the magnetic field at all heights and all pixels by roughly a constant factor, due to an underestimated direct transmission in Stokes V in the telescope model, which was discovered only close to the submission of this work. Thus, all values were compensated, post-inversions, with the ratio of the used transmission and that of the correct transmission (0.605) by assuming the weak-field approximation (i.e., that the magnetic field strength is proportional to the amplitude of the Stokes V profile). While the absolute value of the magnetic field seems to be within those measured in previous literature (i.e., between 2 and 3 kG in the umbra), we abstain from making claims about the absolute values of the magnetic field, but we do study relative differences. Two scans were reconstructed together using MOMFBD for a total of 28 s per scan and 14 frames per wavelength position per LC state. This binning in time at the level of the reconstruction was done for two reasons: in order to increase signal-to-noise ratio in the Stokes profiles, and so that periods of poor seeing, of the order of a second and thus potentially longer than the acquisition time of a single wavelength, would have a much-reduced probability of affecting the final line profile in areas of high spatial gradient (such as in dark fibrils). Combining two scans at the reconstruction level benefits from the fact that MOMFBD overweights images, for the same wavelength, where the quality is highest. Further, the observations were binned spatially in a 2×2 fashion to increase signal and reduce noise. This led to a pixel size of $0''.12$, which is just below the maximum resolution of the SST at this wavelength ($0''.18$) even if this means that we forego Nyquist sampling of the resolution element.

The inversion code NICOLE (Socas-Navarro et al. 2015) was used in NLTE mode with a three-angle Gaussian quadrature for the radiation field. A five-level plus continuum Ca II atom was used as in de la Cruz Rodríguez et al. (2013). The Wittman approach to the equation of state was selected to compute the unfitted thermodynamical variables (Wittmann 1974). The cubic deLo-Bezier solver was selected for the radiative transfer (de la Cruz Rodríguez & Piskunov 2013). We

Figure 1. Top panel: context image in the wing of the Ca II $\lambda 8542$ line at +942 mÅ from line core. Middle panel: context image at -73 mÅ from line core during a flash. Two flashed regions and dark fibrils are visible. The contours indicate the border of the analyzed area (umbra). Bottom panel: the gray contour indicates the umbra, and lighter gray tones indicate the locations of the flashed pixels detected. Each level of lighter gray indicates that the pixel was detected as a flashed pixel for an additional scan in the time series.

include the effect of Ca II isotopic splitting in the inversions (Leenaarts et al. 2014).

A scheme of multiple inversion cycles with ever-increasing nodes was used as suggested by Ruiz Cobo & del Toro Iniesta (1992). The atmospheres were smoothed in between each

cycle, both horizontally and vertically, but the smoothing itself was performed only on the perturbations from the previous cycle. For example, if NICOLE found no way to improve an atmosphere in any given cycle, then no smoothing was applied and the initial-guess atmosphere is carried on for the next cycle. The resulting smoothed low-node inversions were then used as starting guesses for inversions of other line scans close in time. The faculae FAL-C model (Fontenla et al. 1993) was used as the initial atmosphere for every pixel every five scans. For the final run, for each scan, the atmospheres were perturbed with the following number of nodes per variable: temperature—7; velocity—3; microturbulence—1; B_y —1; B_x —1; and B_z —3 (line-of-sight component). Even though one node was included in B_x and B_y , the main impact of this inclusion for the umbra region was to constrain NICOLE not to generate solutions that would lead to strong Q and U profiles, as the signal in Q and U was very low. The weight of the Q and U spectra for the χ^2 computation was half that of Stokes I , and NICOLE generally produced atmospheres with low transverse magnetic field components. Finally, the Stokes V profiles were given 25% lower weight than Stokes I for every wavelength.

Standard inversions in NICOLE usually include a penalty in the χ^2 computation for atmospheres that are not vertically smooth. This is typically referred to as the “regularization.” In this work, the final set of analyzed inversions had effectively a regularization of zero. This choice was made to capture vertical variations to the maximum extent allowed by observations in this line (which we believe should be close to that describable by the seven nodes used for our observations). The disadvantage of such an approach is that seeing-induced fluctuations in the line profile, or other noise sources, can potentially be better fitted by a vertical feature, and thus bumpier atmospheres can be generated where a smooth atmosphere would sufficiently describe the observed profiles. The latter issue is limited by the low amount of fitting nodes employed. The high quality of the observations, especially with regard to seeing, together with the extended reconstruction scheme and destretch technique of Henriques (2012), should also have minimized such effects, especially considering that the umbral photospheric structure, used as reference, is well imaged. Furthermore, the combination of two scans at the reconstruction level (as described above) should have led to an unprecedented reduction in seeing signal. The final analysis adds further robustness, due to the focus on density plots of a large sample of inverted atmospheres and the usage of two-dimensional maps that are averaged over 1 dex thickness in height (i.e., over a slab corresponding to a difference of 1 in the logarithmic optical depth scale).

Since the χ^2 values depend on all wavelengths according to the respective weights in each profile, as well as the regularization, a numerical value for the χ^2 that constitutes a good-enough fit, for the flashed atmospheres, was determined visually from inspecting an array of fits. Any fit with a worse χ^2 than this reference value was selected out from the analysis. Figure 2 shows a fit with a χ^2 at the limit of what was considered sufficiently good. The fits are often as good as those shown in Figures 4, 6, and 8, discussed later in this work.

Portions of the upper-side umbra and left-side penumbra were inverted. In this paper we focus on the umbra, which was selected via intensity thresholding in the line wings followed by an erode morphological operation, performed in order to reduce the area of the mask and minimize the impact of stray

Figure 2. Observed (dashed) and synthesized profiles (solid) from a flashed pixel that were considered to be on the limit of what constitutes an acceptable fit. Any result with a worse goodness of fit was discarded. The plus signs indicate the observed wavelengths.

light from the penumbra (see Figure 1). A total of 37 scans were inverted and analyzed, each 28 s long. The inverted pixels were labeled as flashed pixels if the maximum intensity of the flash spectral feature (i.e., the intensity at any point between -217 and -73 mÅ) was higher than that of the far red wing ($+942$ mÅ). Figure 1 shows the locations of the atmospheres selected in this way. After selecting for quality of fit, the population of flashed column atmospheres numbers 878. A total of 10,989 pixels were considered as quiescent atmospheres by selecting spectra where the maximum intensity between -217 and -73 mÅ was under 0.12 of the fitted continuum intensity across a random, evenly sampled range of scans. The temperature and velocity profiles, as a function of height, were composed into density plots as shown in Figure 9. Other atmospheres from the literature are overplotted for comparison and reference during the discussion. Similarly, magnetic profiles are composed in the density plots of Figure 11.

The dark fibrils in the flashed areas were identified and studied in two different ways: one by manually searching the data cube with CRISPEX (Vissers & Rouppe van der Voort 2012) for dark streaks in the flashes and then examining the corresponding atmospheres in the inversion cubes. The atmosphere and profiles shown in Figure 12 are taken from this analysis. A second identification was performed by taking flash masks and closing any gaps in them with a morphological close operation (with a 3-pixel radius circular kernel or $0''.35$ radius), and then simply subtracting the original flash mask. The flash masks used for this purpose were produced using an intensity criterion lower than that used for flash analysis, namely, a pixel is considered to be flashed if any profile point between -217 and -73 mÅ is brighter than the profile at $+398$ mÅ. This procedure, together with the small morphological mask, objectively detects small dark fibrils enveloped by flashes. In Figure 3 these are visible as the counterparts of the dark holes present in the flashed mask of the same figure. The density plots for the dark fibrils (see Figures 11 and 12) were performed on the population so obtained. These comprise 448 dark fibril atmospheres.

3. Analysis

3.1. Radiative Transfer Results

Some of the flash profiles with a blueshifted emission core are fitted by the inversion code with a model that has strong

Figure 3. Top panel: the gray contour indicates the umbra, and lighter gray tones indicate the locations of the flashed pixels detected using a relaxed intensity threshold below what was used for analysis and not including any quality-of-fit thresholding. Each level of lighter gray indicates that the pixel was detected as a flashed pixel for an additional scan in the time series. Bottom panel: same gray scale scheme, but indicating detected dark fibrils as described in the text. Note that the regions are much smaller, are elongated, and form counterparts to the holes in the map of the top panel. The dark fibril map shown is already selected for fit quality, and thus these are the pixels used for the density plots in Figures 11 and 12.

downflows in the chromosphere, especially close to the transition region, and a hotter temperature profile with a lower gradient than that of the transition region. The fits are good, indicating that the downflowing model is a proper solution to the inverse problem. However, this would conflict with previous works, both theoretical and observational, which invariably conclude that flashes are the result of upflowing material resulting from shocking upward-propagating waves. Moreover, from the point of view of radiative transfer, it is very difficult to understand how a downflowing chromosphere could produce a blueshifted feature.

Some research into this issue revealed an interesting synthesis result. Figure 5 (panel 1) shows the synthetic profile produced by NICOLE with a blueshifted emission from a downflowing model. This profile has been computed with the fine wavelength sampling used internally in the computation. The observations have a coarser sampling, and with the instrumental profile, we obtain the profile shown in the bottom left panel, which reproduces very well the observed profile of the flash shown in Figure 4.

Figure 4. Observed (dashed) and synthesized (solid) profiles and atmosphere for one of the most extreme flashes, here reproduced with a hot, strongly downflowing, upper chromosphere. Note the strength of the flash ($4\times$ enhancement), the quality of the fit, and that, for the Stokes I profile, the minimum is close to 0.10 of the average continuum quiet-Sun intensity.

Figure 5. Top left: synthesized Stokes I profile from the downflowing atmosphere shown in Figure 4. This profile has no instrumental or sampling effects applied. Top right: synthesis in the same atmosphere but with all velocities zeroed. Bottom left: same as the top right panel, but with instrumental effects applied; the dot-dashed line is the observed profile. Bottom right: same as the top left panel, but with the sign of the velocities swapped.

If we now take the model and artificially switch off the velocity, we obtain the profile in the top right panel. Notice that, instead of a single emission feature, this model is producing emission with a central self-absorption, similar to what is often observed in Ca II H and K, but with a deep and flat absorption core. In this situation we actually have two peaks. Now, with a suitable velocity gradient, it is possible to introduce a peak asymmetry such that the red peak is almost completely washed out and only the blue peak remains visible. Notice that the red peak was still visible in the first synthetic profile (top left panel), but because of its lower amplitude, not only is it weaker, but it is also almost completely lost when convolved with the instrumental profile and resampled to match the observations (bottom left panel). If we artificially flip the sign of the velocity, we obtain the opposite effect, with the blue

peak disappearing and leaving the red one (bottom right panel). This is an interesting radiative transfer result in itself, as one can have atmospheres generating apparent single emission profiles with Doppler shifts of opposite signal to that actually present. Although not in flashes, emission features with Doppler shifts opposite to the actual flow have been found before (Scharmer 1984; de la Cruz Rodríguez et al. 2015a). In those works it was found that strong flows were shifting opacity from the red wing into the blue wing, thus causing emission features in the red to be enhanced and similar features in the blue to dampen (and also vice versa in Scharmer 1984). A strong velocity gradient, starting at the upper layers, was a key ingredient, and the same effect was found to play a role in the peak asymmetries seen in Ca II grains and flares (Carlsson & Stein 1997; Kuridze et al. 2015).

With higher spectral sampling and for this particular observed profile, perhaps we would have found that such a small red peak was not present, thus having enough constraint in the inversions so that the downflowing solution would not be selected. On the other hand, this is a particularly extreme pixel in terms of flash intensity, with an enhancement of 4 times the quiescent intensity (normal values being around 2). It may be that, if such hot downflows are present in the umbra of sunspots, the red attenuated peak will be very difficult to detect with any instrumental setup. Further, note that, for this particular example, we do not have an upflowing atmosphere that reproduces the observed profiles equally well even if such a solution exists.

If one decides, based on previous literature, that the downflowing solutions are not real, then one can penalize those solutions in the χ^2 computation or outright remove them from the analysis. Perhaps a better way to resolve ambiguities regarding atmospheres that are very different in the upper chromosphere or lower transition region (see full discussion of their properties in Section 3.4) may be to simply use transition region or upper chromospheric diagnostics, such as the ones available with IRIS, by inputting additional temperature or velocity constraints directly into the chromospheric inversions, or fully inverting them together. Given that the downflowing atmosphere is about 500 K hotter than the upflowing solution, just below the transition region, it may be possible to decide between the two families of models with an additional temperature diagnostic that samples such heights, without having to invert multiple lines together.

Finally, we have obtained a third set of solutions. In low-node inversions these look similar to the downflowing family of solutions, but when increasing the number of nodes to 7, the fits become considerably better with a second inflection from a downflow to an upflow above $\log \tau_{500} = -4$. The peak of the downflows in such atmospheres tends to be around where quiescent and flashed atmospheres diverge, at $\log \tau_{500} = -3$. An extreme example of such a fit and respective atmosphere is shown in Figure 6. Due to the reduced sensitivity of the line in the upper layers, this solution may not be indicating any real flows aside from the purely downflowing solution. The presence and proper modeling of NLTE effects do provide some sensitivity to layers all the way up to the transition region, as different incoming radiation fields from above will lead to different population levels. However, this sensitivity is mostly in temperature.

In this paper we discuss both main families of solutions (downflowing and upflowing) separately.

Figure 6. Top panels: observed Stokes I and V profiles (dashed) and respective fits (solid) for a flashed pixel. Bottom panels: fitted atmosphere, featuring a velocity stratification with both up- and downflows.

3.2. Inversion Results of Flashed Profiles

In Figure 7, we show temperature and velocity maps for three different layers for a scan where multiple flash fronts are progressing. Diffuse regions with velocities around 1 km s^{-1} for the upper photospheric layer ($\log \tau_{500} = -1.5$ to -2.5) are visible. The contrast is generally low at such heights. As in de la Cruz Rodríguez et al. (2013), the inner penumbra is mostly upflowing. As one goes up to $\log \tau_{500} = -2.5$ to -3.5 in height, the amplitude of all flows seems to increase, and so does the contrast. At this height the umbra shows a mixed picture of up- and downflows. Progressing higher to between -3.5 and -4.5 , the inner penumbra shows a higher abundance of downflows, in the 1 km s^{-1} range, and the whole map has, again, lower contrast. Some relation between strong downflows and hotter patches is visible in these maps.

3.2.1. Downflowing Atmospheres

As shown in the first row of density plots of Figure 9, where darker indicates more points, the inverted atmospheres split into two clear branches in the inverted velocity. In the second row we selected all atmospheres with downflows stronger than 3 km s^{-1} (a total of 527 atmospheres). The downflowing flashed solutions feature a hot region that slopes up from $\log \tau_{500} = -3$ to $\log \tau_{500} \sim -4.5$, with a much lower gradient than that of the transition region. The relative increase compared with the upflowing flash solutions and the average quiescent umbra atmospheres is 1000 K at $\log \tau_{500} = -4$. This is about the same relative increase as in de la Cruz Rodríguez et al. (2013) even if, in that work, the effect of the flash in temperature was more of a flattening with no atmospheres going above 4000 K before the transition region (similar to the upflowing results in this paper). In both cases the atmospheres diverge at $\log \tau_{500} = -3$. The velocity stratification slopes from just over a 10 km s^{-1} downflow at $\log \tau_{500} = -5$ to close to rest at $\log \tau_{500} = -3$.

This is the first report, to our knowledge, of a strongly downflowing semiempirical atmosphere, in the upper chromosphere, for the umbral flashes. Looking at other aspects of this sunspot, one finds, rooted in the umbra, the footpoint of a coronal loop (or footpoints of multiple loops) as observed in

Figure 7. Top row: same images as Figure 1, but with arrows added. Left column: inverted temperature maps. Right column: respective velocity maps. Second row: the mean over a slab from the upper photosphere to lower chromosphere ($\log \tau_{500} = -1.5$ to -2.5). Third row: the mean taken over $\log \tau_{500} = -2.5$ to -3.5 . Fourth row: the mean from $\log \tau_{500} = -3.8$ to -4.8 . Bottom row: magnetic field averaged over $\log \tau_{500} = -1.5$ to -2.5 (left) and magnetic field map averaged from $\log \tau_{500} = -3.8$ to -4.8 (right). The left arrow indicates an area of enhanced magnetic field in the upper layers. The right arrow indicates an area of reduced magnetic field.

the EUV in the 171 Å bandpass with AIA (see Figure 10). Such loops are known to be strongly downflowing in the lower corona and transition region and are most likely what earlier literature calls sunspot plumes (Damasch et al. 2008), regions of enhanced emission in lines formed in the 10^5 – 10^6 K range and typically colder than the surrounding corona (e.g., Noyes et al. 1985; Brosius 2005). Such plumes occur in a majority of sunspots (but not in all and rarely rooted in the umbra), with downflows of up to 25 km s^{-1} (Maltby et al. 1999). The relation between downflows in plumes and higher empirical temperatures seems to be causal, as both parameters tend to coevolve in time (Brosius 2005).

Downflows directly over the umbra in the transition region have been observed as early as Dere (1982) with 5 – 20 km s^{-1} steady flows and up to 150 km s^{-1} in localized channels. The

Figure 8. Top row: observed (dashed) and synthetic (solid) profiles for a flashed pixel that was fitted with an upflowing result. Bottom panels: atmospheric properties that generate the synthetic profiles, atmospheric parameters as labeled.

early review of Maltby (1997) shows that such observations were not an isolated case. More recently, extreme downflows up to 200 km s^{-1} have been observed in the transition region above sunspots by Kleint et al. (2014), which were interpreted as coronal rain. $H\alpha$ observations of coronal rain above sunspots have been shown to have average velocities of 60 km s^{-1} (Vissers & Rouppe van der Voort 2012). A recent strong downflow event in the umbra of a spot, displaying EUV emission with properties consistent with those of plumes, has been detected in both transition region and chromospheric lines by Kwak et al. (2016) with evidence for excitation of the chromospheric 3-minute oscillations. Furthermore, on a spot displaying a coronal loop rooted in the dark umbra, similar to the one in this work, Chitta et al. (2016) found supersonic downflows in the transition region and in the upper chromospheric line of $\text{Mg II k } \lambda 2796$ of around 100 km s^{-1} . Perhaps more interesting is that they found a velocity of 15 km s^{-1} in the transition region lines at the very footpoint of the structure. They found such a value to be consistent with a post-shock flow, in terms of mass flux conservation and following from the Rankine–Hugoniot condition for isothermal shocks, from the 100 km s^{-1} flow. Such a downflow of 15 km s^{-1} is just above our topmost inverted values for the transition region in the downflowing family of solutions, which can be seen in Figure 9 at $\log \tau_{500} = -5.5$ (corresponding to the steep transition temperature slope). Our sensitivity at such heights is limited but present (as discussed in Section 3.1), and the velocity slope is gradual and has very little spread in the density plots. Going further back, evidence for downflows and upflows coexisting within a 0.3 element (SUMER slit’s width) in the transition

Figure 9. Density plots (i.e., darker meaning a higher concentration of points). Left column: temperature stratification vs. $\log \tau_{500}$. Right column: velocity stratification vs. $\log \tau_{500}$. Top row: flashed atmospheres, all solution types. Second row: flash atmospheres, downflowing solutions only. Third row: flashed atmospheres after downflowing results were filtered out. Fourth row: atmospheric models for the quiescent umbra. Models found in the literature for the same structures and in optical depth scale are overplotted: the solid line is MaltbyL, the dotted line is the dark umbra model of Socas-Navarro (2007), the dashed line is the first component of the time-dependent strong-flash model from Socas-Navarro et al. (2001), and the dot-dashed line is the second component. The dashed velocity profiles are also from the latter two-component model.

region of the umbra has existed since Brynildsen et al. (2001). If these observations correspond to one component of a siphon flow (Cargill & Priest 1980), one should remember that while the inverse Evershed flow is observed well outside the umbra, it would geometrically complement any umbral downflow observed in the higher layers, and it has been observed to have amplitudes topping, similarly, 15 km s^{-1} .

As counterevidence to the idea of strong chromospheric downflows, even in the presence of transition region flows, recently Straus et al. (2015) found a steady supersonic downflow in the transition region of the umbra of a sunspot using IRIS but no chromospheric downflow in the cooler passbands. They find their results compatible with the model of a siphon flow, mainly due to the stability of the observed flows.

Given the evidence from previous works for umbral downflows that extend to the chromosphere and lower transition region, one cannot discard the inverted downflowing

Figure 10. Plume structure visible in AIA 171. The bright contour outlines the dark and largest umbra as traced from AIA’s 1700 passband (simple intensity masking), and the upper two-thirds match approximately with the umbra contours shown in Figure 1.

solutions as merely a radiative transfer curiosity and has to consider the possibility that the hot-downflow fits are capturing an actual hot, upward-propagating shock occurring against a strong downflow. It can even be that a second shock from the infalling material into a higher density layer, similarly to that reported by Chitta et al. (2016), is occurring at the same heights as the flash, and thus interfering with or modulating the shocks that would normally occur from the steepening of the 3-minute oscillations. If hot chromospheric downflows are real, it may be that the presence of a sunspot plume, rooted in the umbra, either is critical or greatly increases the possibility of detection. A lot of our confidence in upflowing models comes from syntheses, in hot upflowing atmospheres (upflowing around $\log \tau_{500} = -4$), that successfully reproduce the sawtooth pattern (Bard & Carlsson 2010). We suggest that a similar procedure should be attempted in future work on the hot downflowing model atmospheres.

3.2.2. Upflowing Atmospheres

Synthetic and observed profiles, as well as the atmospheric parameters of a single pixel fitted with a classic upflowing solution, are shown in Figure 8. The full spread of such solutions is best seen in the third row of the density plots in Figure 9, where all atmospheres with any downflow over 3 km s^{-1} were removed (for a total of 351 atmospheres). From $\log \tau_{500} = -3.5$ to -4.5 these show a spread in temperature that goes from about 4100 K, following a flat top just above the one-dimensional umbral core model “L” by Maltby et al. (1986) (their Table 9; from now on “MaltbyL”), shown as a solid line, to as low as the allowed minimum at 2500 K. The highest density of atmospheres (which the mode of the distribution traces) is close to the upper range, around 3900 K, and seems to match that obtained by de la Cruz Rodríguez et al. (2013) for the same heights. Compared with that work, our spread in temperatures is somewhat higher, but

Figure 11. Density plots for the magnetic field stratification (line-of-sight magnetic field component vs. height in $\log \tau_{500}$). Top left: flashed models. Top right: dark fibril models. Bottom: quiescent models.

the quantity of the inverted pixels and scans in this work is also much higher. At this height interval, the upflowing flashed atmospheres are hotter than the quiescent case, but only considering the mean and the mode. At $\log \tau_{500} = -5$ the solutions are always hotter than any quiescent atmosphere. This appears to be from a shift of the very high temperature gradient region, corresponding to the beginning of the transition region, to a lower optical opacity, i.e., the transition region is about half a dex deeper in the flashed models than in the quiescent models. This aspect, together with the slight dip in temperature around $\log \tau_{500} = -4$, seems to match the two components from Socas-Navarro et al. (2000a), overplotted in Figure 9. The difference is that our flashed and quiescent atmospheres, at the $\log \tau_{500} = -4$ dip, have the highest density of atmospheres at temperatures higher than their respective two-component analogs. Furthermore, our quiescent atmosphere is not strongly downflowing, as is the case with the dashed component from Socas-Navarro et al. (2000a).

A slight enhancement, but only up to a couple hundred kelvin, when compared with both the quiescent case and the lower heights, is visible around $\log \tau_{500} = -3$. This is where the flashed atmospheres clearly depart from the quiescent case in all variables and for all families of models. It is the same height of divergence as that of de la Cruz Rodríguez et al. (2013). This enhancement is very similar to that plotted for all models present in Socas-Navarro et al. (2000a), but is different in nature from that of de la Cruz Rodríguez et al. (2013), where the divergence between flashed and quiescent atmospheres starts as a change of slope in temperature. For this work, and for both components of Socas-Navarro et al. (2000a), there is a visible “bump.”

As far as the velocity is concerned, the value of -5 km s^{-1} at $\log \tau_{500} = -5$ and the shape of the chromospheric profiles match those obtained by de la Cruz Rodríguez et al. (2013) and Socas-Navarro et al. (2000b). In velocity it is more visible that the divergence between the families of models starts as low as $\log \tau_{500} = -2$. At the photosphere, even though our sensitivity is limited at such layers, all flashed atmospheres are close to rest.

3.3. Magnetic Field Response

Both in the density plots and in the magnetic field maps (see Figure 11 and the region highlighted by the right arrow in Figure 7), all families of flashed solutions lead to a reduction in

the magnetic field when compared to the quiescent case. The spread of atmospheres prevents a conclusion about stratification itself, but an average reduction is clearly present for nearly all flashed pixels when averaging over the column. This leads us to a tentative explanation for the observed magnetic field reduction as an increase in the adiabatic gas pressure from the shock, pushing the magnetic field lines away from the flashed areas.

For some maps one is tempted to infer that there is also a counterpart magnetic field enhancement, at the border of the reduction. One gets the strongest impression at the borders of flashes, such as the one highlighted by the left arrow in Figure 7. However, we are unable to claim that this counterpart enhancement is above the spatial inversion noise.

In a broader context, this work adds to the recent body of evidence for the existence of magnetic field oscillations in sunspots, at least in the chromosphere (de la Cruz Rodríguez et al. 2013), a debated topic that remains unsolved (e.g., Rutten 2010). An alternative explanation for the magnetic field reduction is simply observational, in that the normally reduced field in the higher layers (where we could expect some fanning out of the field lines, even if known to be limited in the umbra) is just not captured by the photospherically dominated Stokes V profiles unless there is a flash providing some signal from the upper layers. This effect would be similar to that proposed by Collados (2002) and Khomenko et al. (2003), where opacity variations explain much of the small apparent field modulation observed in earlier works.

3.4. Inversion Results of Quiescent Profiles

For the quiescent models (see Figure 9), we find that the temperature profiles tend to be flat from $\log \tau_{500} = -1.5$ up to $\log \tau_{500} = -3.5$. Higher up we get a large scatter of models. MaltbyL, plotted as a solid line in Figure 9, happens to constitute a good average profile to our scatter, with the exception of MaltbyL being about 100 K cooler between $\log \tau_{500} = -1$ and -3 . This good match is the reason why we chose to plot this model from the earlier LTE model literature. However, MaltbyL is an unusually hot model when it comes to umbral models for the layers above $\log \tau_{500} = -2$. It is also a relatively flat model (e.g., compare its profile with the other reference atmospheres plotted in Figure 9). The chromospheric dark umbra model of Socas-Navarro (2007) (the dotted atmosphere in Figure 9) has a more complex stratification, with a dip below 3000 K above $\log \tau_{500} = -4$, which is on the cooler limit of our results. Such a temperature drop below 3000 K in the umbra is supported by the multiline model of Fontenla et al. (2009) and the millimeter observations of Loukitcheva et al. (2014), with the caveat that the latter may be valid only for some spots, as the brightness in the radio range, similarly to what is observed in the optical, can vary from spot to spot (Iwai et al. 2016).

Similarly to this work, the inversions of high-resolution Ca II $\lambda 8542$ data by de la Cruz Rodríguez et al. (2013) resulted in a wide range of atmospheres for the quiescent phase, with models as cold as 2500 K and a near-continuous progression up to about 3500 K at $\log \tau_{500} = -4$. In this work, the quiescent temperature profiles most similar to such models, and to that of Socas-Navarro (2007), tend to occur close to the umbra/penumbral boundary, especially in the disk-center side umbra (see Figure 7). However, we obtain a clear range of temperatures that peak higher, at just about 4000 K at

$\log \tau_{500} = -4$, which was not observed in that previous report. Target-wise, the main observational differences between de la Cruz Rodríguez et al. (2013) and this work are the size of the sunspots, larger in the present work, and the viewing angle ($\mu = 0.87$ vs. $\mu = 1$ in this work). Considering the impact of selection effects, the most unique characteristic of this work is the sheer amount of inverted pixels, with about 10,989 quiescent pixels analyzed, which could lead to a larger scatter of atmospheres in the upper layers, but the obtained velocities do not show such scatter. In fact, the scatter of models in velocity seems to be lower than that of de la Cruz Rodríguez et al. (2013). Finally, the spots were also observed at different phases of the cycle, with the earlier work being close to the minimum of the previous sunspot cycle and this work being just after the maximum. There is evidence that umbral temperatures, at least at photospheric levels, fluctuate with solar cycle (see, e.g., Albregtsen & Maltby 1978; Maltby et al. 1986; Rezaei et al. 2012). In this sense, due to the similarity of approaches and data, de la Cruz Rodríguez et al. (2013), together with this work, add to the body of evidence that the temperature of the umbra of sunspots does vary with cycle, with later sunspots being hotter in the upper chromosphere. This is further reinforced if one considers that the model that best matched our results from the old LTE literature was the late-cycle model of Maltby et al. (1986).

In terms of velocity the quiescent phase shows the top end of the distribution downflowing at about 1 km s^{-1} in the upper layers, but consistently at rest in the photosphere with a very small scatter. The presence of a weak downflow in the upper layers is consistent with the past literature and the idea of a transient strong upflow followed by a slow downflow first put forward by Beckers & Tallant (1969), but, as shown in Figure 9, the small scatter of solutions includes the at-rest case.

Magnetic-field-wise, as shown in Figure 11, quiescent atmospheres show a progressive reduction of average field strength and of the range of measured values with increasing heights. The lower end of the distribution reduces in field strength from approximately 2000 G in the photosphere to a narrow range of inverted values at 1500 G in the upper chromosphere.

3.5. Inversion Results of Dark Fibrils

From both the manual and automated analysis, one finds that the typical dark fibril Stokes I profile is not only significantly darker than a flashed profile at the flash-peak wavelengths but also slightly darker in the wings (up to, at least, $\pm 1 \text{ \AA}$), indicating a photospheric connection. For an example see the profiles in Figure 12. The profiles of the darkest fibrils are more similar to quiescent profiles than to those of the flashed atmospheres, with the Stokes I profiles not showing the flash emission in the line wings, and the Stokes V profiles not showing the abnormal, reversed-polarity, blue peak. However, the Stokes V profiles show a flatter blue half and an attenuated red peak when compared to the quiescent case (see Figure 12), as one would expect if the blue trough had been redshifted. From the density plots of the inversions (bottom panels of Figure 12) we find that the observed dark fibril profiles are reproduced with atmospheres that are similar to the flashed atmospheres in terms of velocity and temperature stratifications, albeit with lower amplitudes. Dark fibril profiles are reproduced with flows in the upper chromosphere that are about half those found for the flashed profiles, peaking close to

Figure 12. Top: same image of a flash with dark fibrils, with and without arrows, at -73 mÅ from core. The contour traces the umbra mask. The left arrow points at a pixel in the flashed area, and the right arrow points at a pixel in the dark fibril. The Stokes I and Stokes V profiles on the left are for the dark fibril pixel. Those on the right are for the flashed pixel. Dashed lines trace the observed profiles, solid lines the synthetic profiles. The dotted line is from a typical quiescent atmosphere. The plus signs indicate the observed wavelength positions. The bottom row plots the inverted temperature and line-of-sight velocity for the dark fibril (solid line), density plots for the dark fibrils that were automatically detected (shades proportional to density), the mode of the downflowing flashed atmospheres (short-dashed line), and the mode of the upflowing flashed atmospheres (long-dashed line).

5 km s^{-1} at $\log \tau_{500} = -5$. The temperatures are also lower than the flashed case, which might help explain their relative darkness, together with any NLTE effects that NICOLE might be capturing (to be addressed in a future publication). They are hotter than the average quiescent atmosphere. The majority of the dark fibrils detected are downflowing. Considering that a good portion of the observed dark fibrils should be short dynamic fibrils, known to have up- and downflowing phases (Roupe van der Voort & de la Cruz Rodríguez 2013), one must be open to the possibility that something about our intensity detection method is preferentially selecting the downflowing stages. It may also be that short dynamic fibrils are the darkest during their downflowing stage when observed at $\mu = 1$.

The inverted average magnetic field strength (see Figure 11) seems to occupy the values between those obtained for the quiescent and the flashed case. The exception is the magnetic field above $\log \tau_{500} = -4$, where both dark fibrils and flashed atmospheres do not show the same progressive drop with height that the quiescent atmospheres do.

These results are consistent with dark fibrils being primarily caused by atmospheric inhomogeneities that affect the propagation of the flash. Since we are likely resolving the same two components put forward by Socas-Navarro et al. (2000b), it makes sense that at least one of the components here observed would have stronger amplitudes in velocity when compared to the previous literature. As discussed above, upper-layer flows from an unusual loop rooted in the umbra may be partially responsible in generating stronger and more easily identifiable components (at least downflowing ones). Generalizing to other observed sunspots, the existence of a different flow structure across the umbra would provide the inhomogeneity that allows for the existence of short dynamic fibrils/spikes and dark umbral fibrils in the first place. One scenario is that the upper-layer flow modulates the height at which the shock front occurs. More specifically, in such a scenario, from the frame of reference of the downflowing material, the shock that generates the umbral flash would still be propagating upward in an isotropic wave as generally understood, but from an external point of view, a visible shock propagating along such a downflowing region would appear lower than one propagating in the upflowing regions. This would lead to visually distinct features separate in height. Furthermore, if the velocity gradient is sufficiently low (i.e., if a downflow extends deep enough into the chromosphere), then a downflow could hide the flash brightening into a deeper layer, causing the profile to show both a reduced blue emission peak and a redshifted line core, exactly like the one shown in Figure 12.

4. Concluding Remarks

We present NLTE inversions of chromospheric high-resolution spectropolarimetric observations of umbral flashes, discriminated by type of feature. We find two families of solutions for umbral flashes. One is upflowing in the chromosphere with the transition region moving lower in height when compared with the quiescent phase, in line with previous results. The second is strongly downflowing, with downflows in excess of 5 km s^{-1} in the upper chromosphere and increasing up to just under 15 km s^{-1} in the transition region. These feature a region with lower temperature gradient in the chromosphere but hotter than the upflowing family of solutions at such heights. This new family of solutions for

flashes is either a radiative transfer effect that may or may not have counterparts in the Sun (and thus a pitfall to watch out for and invalidate) or a real solution reported here for the first time. Given the presence of a coronal loop, visible in the EUV 171 Å bandpass with AIA (up to 10^5 K), and the previous literature on the flows of these structures, as well as recent discoveries of downflows in the chromosphere of the umbra of other sunspots, we propose that both the downflowing and the upflowing solutions are real and extremes of a commonly occurring inhomogeneity in flows. Such inhomogeneity, at smaller scales, would help explain the visibility of phenomena such as short dynamic fibrils, spikes, and dark features observed in flashes in general. Such downflows and their presence in dark fibrils also provide a direct piece of the puzzle in the recently discovered relationship between short dynamic fibrils and umbral microjets (Nelson et al. 2017).

We also provide models for the quiescent umbra that are, on average, flatter and hotter in temperature stratification than most previous literature but that agree with the late-cycle umbral model of Maltby et al. (1986). With this work focusing on a late-cycle sunspot, together with de la Cruz Rodríguez et al. (2013) obtaining lower average temperatures with a similar study for an early-cycle spot, this constitutes additional evidence for the hypothesis that the umbrae of late-cycle sunspots, at least in the chromosphere, are indeed hotter than those of early-cycle sunspots. This result is also the first chromospheric NLTE empirical study in support of the Maltby late-cycle umbra model.

We find supporting evidence, from the NLTE inversions, for the previous LTE literature on umbral models that seemed to indicate that the magnetic field in the umbra only has a slight drop in strength from the photosphere to the chromosphere. Perhaps more importantly, we find that flashed areas show lower magnetic field strengths on average. Speculatively, the latter may be due to an increase in gas pressure with the shock pressure pushing field lines away. Alternatively, higher sensitivity to the upper layers of the atmosphere, caused by the flash, may lead to success in reproducing an ever-present reduction of the field with height.

We find that the darkest fibrils observed in the flashes have Stokes profiles that are distinct from both flashed and quiescent regions. While similar to those of the quiescent umbral atmosphere, clear differences are invariably fitted with flash-like thermodynamical properties, albeit with reduced amplitudes. Given the ensemble of results presented in this paper, it is tempting to interpret the observed dark fibrils as a manifestation of an inhomogeneous flow structure in the umbra, possibly affected by transition region or even coronal flows, affecting the speed at which the shock wave from the flash propagates from an external point of view.

As a final note, it is interesting that for any family of solutions, bright flashed atmospheres and their dark features are always strongly flowing, whereas quiescent atmospheres are always very close to rest.

We would like to thank the anonymous referee for relevant questions that led to improvements in the quality of the results. We would also like to thank Peter Sütterlin for assisting with the observations. We acknowledge support from Robert Ryans with computing infrastructure.
