Abstract. Roll-to-roll printed electronics (R2RPE) is proved to be an effective way to fabricate electrical devices on various substrates. High precision overlay alignment plays a key role to create multi-layer electrical devices. Multiple rollers are adopted to support and transport the substrate web. In order to eliminate the negative effect of the machining error and assembling error of the roller, a whole roll-to-roll system including two aerostatic bearing devices with arrayed restrictors is proposed in this paper. Different from the conventional roller, the aerostatic bearing device can create a layer of air film between the web and the device to realize non-contact support and transport. Based on simplified Navier-Stokes equations, the theoretical model of the air film is established. Moreover, the pressure distribution of the whole flow field and single restrictor in different positions are modeled by conducting numerical simulation with Computational Fluid Dynamics (CFD) software FLUENT. The load capacity curves and stiffness curves are generated to provide guidance for optimizing the structure of device. A prototype of the aerostatic bearing system is set up and the experiment tests are carried out. For the proposed aerostatic bearing roller with diameter of 100 mm and length of 200 mm, the experimental results show the aerostatic bearing method can achieve the position accuracy in a range of 1 μm in the vertical direction of the web, which is much better than that using existing methods.

Keywords: Roll-to-roll printed electronics; Micro-positioning; Aerostatic bearing; CFD simulation; Deviation elimination

1. Introduction

Printed electronics has been regarded as a novel technique to create large-scale electrical devices on flexible substrates. Moreover, the roll-to-roll process can offer this technology a remarkable solution to manufacture multipurpose, flexible and low-price

electronic devices such as organic thin film transistor (OTFT), organic light-emitting diodes (OLED), e-paper, exible displays, radio-frequency identification devices (RFID), organic photovoltaic (OPV), and so on [1, 2]. Different from the conventional printing process which only print a single-layer structure, the printed electronics needs to fabricate electrical devices with different materials printed on the same substrate area. Therefore, the alignment accuracy between different layers is the critical demand to guarantee the high quality of the electrical devices. In this regard, an high-precision multi-layer alignment system is urgently needed [3, 4, 5].

In order to exhibition the general R2RPE fabrication process, a schematic diagram of the R2RPE is shown in Fig. 1. The substrate web is released from the unwinding roller, then transported to the pre-processing module for surface treatment. The web tension is detected and adjusted to ensure the web moving smoothly. The web guiding mechanism is generally adopted to adjust the cross-direction position of the web. The printed web will be transported to the post-processing module for drying, heating, cooling, etc, then rolled up by the rewinding roller. The multi-layer printing module is the key module to manufacture multi-layer electronic devices. During the printing process, The multi-layer printed electronics alignment is important to ensure the performance of the electronic devices, which can be regarded as a plane alignment process [6]. The position error of the web in three directions, i.e., machine direction (MD), cross direction (CD) and rotational direction (RD), will cause the misalignment of the printed electronic material in different layers. The misalignment is regraded as the most important alignment accuracy index of the R2RPE device, which is called overlay alignment error [7, 8, 9]. The overlay alignment error is generally caused by various factors. The uneven tension of the web will cause extra stretch or wrinkle of the web. Moreover, the machining errors and assembling error of the rollers such as cylindricity error, eccentric error and parallelism error, will cause the dynamic position error of the web. The overlay alignment accuracy of the existing R2RPE technology can realize about 40-100 μ m shown in the the current literature, thus the resolution of the printed pattern is restricted to about 100 μ m [10, 11]. For all kinds of high-performance electronic products such as high definition exible displays which need a print resolution of less than 10 μ m, existent alignment accuracy is not enough to meet the requirement .

In order to improve the pattern resolution of printed electronic device, many reseachers have conducted various methods to reduce overlay alignment errors. To reduce tension fluctuation, a tension adjustment mechanism called "dancer" are widely used to actively or passively compensate the tension deviation [12, 13, 14]. Charge-coupled device (CCD) camera are usually adopted to detect the overlay offset [8, 15]. A series of control algorithms combined with various actuating mechanism are adopted to compensate the overlay error. A feedforward control strategy is presented to reduce position error from the upstream span based on a theoretical model which combines the MD and CD errors to an oblique MD model [16, 17]. In order to reduce the overlay alignment error with a decoupling control strategy, a R2RPE equipment is

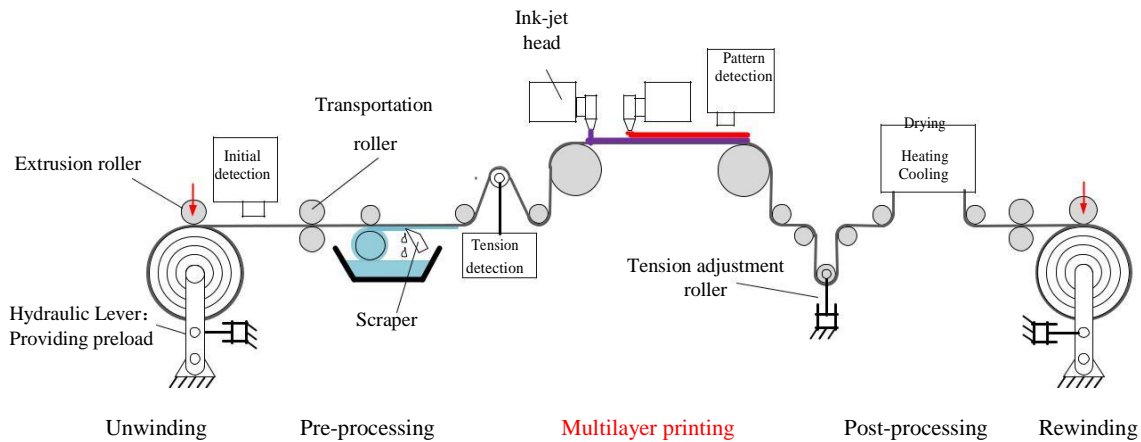

Figure 1. Flow chart of a conventional roll-to-roll inkjet printing process.

proposed with the rotary actuators and linear actuators eliminating the errors in two direction respectively [18, 19]. Although the overlay alignment errors can be reduced greatly based on the above method, but the R2R system usually needs to halt and adjust. Thus the work efficiency will be greatly affected. The compliant mechanism can be adopted to design precision positioning mechanism considering its advantages of eliminated backlash and friction, no need for lubrication, reduced wear and noise, and monolithic configuration [20]. A flexure-based XY stage is proposed to compensate the alignment errors for roll-to-roll printed electronics [21]. A R2R multi-layer printing prototype is proposed based on compliant mechanisms [22, 23]. When the position error of the roller is detected, the compliant mechanisms can actively adjust the roller posture to eliminate the error precisely. Moreover, a flexure-based roll-to-roll printing system is developed which can achieve sub-nano scale print resolution. The roller posture can be adjusted in real-time [24, 25]. Therefore, the compliant mechanism can be used to improve the error eliminating efficiency and accuracy. However, the dynamic property of the system would be weak since the stiffness of compliant mechanisms in the working direction is relatively low. Overall, the existing techniques adopted to improve the alignment accuracy rarely account the errors caused by the conventional roller. The alignment errors caused by these dynamic position deviation are extremely difficult to be eliminated. Devitt et al. proposed a method to separate the web and the roller by using porous bearings. But they just use it for web support while not consider the transport accuracy of the web [26].

Considering the above facts, the design and study of an aerostatic bearing system with a novel aerostatic bearing module to eliminate the dynamic position error of the web is presented in this paper. A pair of aerostatic bearing devices with arrayed restrictors are adopted to separate the web and the roller. The aerostatic bearing device can generate a thin air film to prevent contact and friction between the web and the roller. By this mean the machining and assembling errors of the traditional rollers will have not a effect on the web. The remainder of this paper is structured as follows: Section

It presents the prototype description and design consideration of the aerostatic bearing system. In Section III, the theoretical analysis of the air flow field is established in detail. The CFD simulations for the optimization of the arrayed restrictors are shown in Section IV. Moreover, the prototype of whole roll-to-roll system is set up, and experimental tests are carried out to investigate the performance of the aerostatic bearing device in Section V. Finally, the work is concluded and expectation of future works are presented in Section VI.

Figure 2. Overlay alignment error model.

2. System design

2.1. Design consideration

Since the overlay alignment accuracy is the critical limit to the R2RPE system, the overlay alignment error should be eliminated as much as possible. The overlay alignment error model is shown in Fig. 2. The posture deviation of the ink-jet printer, stretching of the web caused by tension variation, machining and assembling errors of the roller have enormous negative effects on the alignment accuracy. The error caused by the posture of the inkjet printer and the web tension can be eliminated by preset and control strategy optimization respectively. However, the dynamic error caused by the rolling roller is hard to be compensated. As shown in Fig. 3, the machining and assembling errors of the traditional rollers will lead to cylindricity error, eccentric error and parallelism error between different rollers. These errors will lead to position fluctuation and uneven tension distribution of the web. The uneven tension distribution will cause uneven stretch deformation of the web, which will affect the position of the ink on the web. All these factors will reduce the accuracy of the multi-layer alignment. However, the dynamic position error caused by the rollers can hardly be eliminated in real-time, which

will increase the control difficulty. Therefore, the key to solve this issue is to design a novel support and transport mechanism which can replace the rolling roller contacting to the web.

Figure 3. The negative effects of the conventional rolling roller on overlay alignment accuracy.

Figure 4. Prototype of the aerostatic bearing system: (a) overall view, (b) static rollers, and (c) passive tension adjustment mechanism.

2.2. Description of the whole system

According to the above design considerations, a novel aerostatic bearing system is proposed as shown in Fig. 4. It can be seen that the whole system assembled on a precision installation plate consists of five modules, i.e., the unwinding module,

the tension detection module, the aerostatic bearing module, the tension adjustment module, and the rewinding module.

The aerostatic bearing module is the core part of the system which contains a pair of static rollers. As shown in Fig. 4(b), the static roller mainly includes a cylindrical sleeve with arrayed restrictors on the surface, two side covers, an air inlet, and a high accuracy manometer to detect the air pressure. A high-precision laser sensor (LK-H020, KEYENCE) with 6 mm measurement range and 20 nm resolution is adopted to detect the oat height and the vibration performance of the web. Through the duration of the external air supply, the cavity of the roller is lled with compressed air, an air lm will be formed by the arrayed restrictors between the substrate web and the static roller. The web and the static roller is separated from each other by the generated air lm, thus no contact and friction would exist between the two surfaces. By the method, the position of the web will not be affected by the adverse factors of the conventional rolling rollers.

The unwinding module consists of a mechanical expansion shaft driven by a servo motor (ECMA-C10604SS, DELTA). The diameter of the shaft can be adjusted by the handle to install or uninstall the web reel. The diameter of the web reel changes along with the web transport. In order to maintain constant velocity and tension of web, the velocity and torque of the servo motor should be varied. A laser sensor (IL-S065, KEYENCE) is adopted to detect the diameter variation of the web reel for velocity and torque control of the servo motor. The rewinding module is assembled like the unwinding module.

The tension detection module and the tension adjustment module are formed to control the web tension. In the tension detection module an idler roller is assembled on two tension detectors (LX-030TD, MITSUBISHI). The load on the tension detector will be recorded to calculate the web tension. The obtained tension will be used for the servo control feedback and load capacity calculation of the aerostatic bearing roller. As shown in Fig. 4(c), a passive tension adjustment mechanism is adopted in the tension adjustment module. The ends of an idler roller are assembled on two linear guides with slider connected to a spring. This tension adjustment mechanism will provide preload tension and neutralize tension fluctuations passively. The other series of idler rollers are assembled on the mounting plates.

2.3. Selection of the restrictor

Different structures of the restrictors have different effects on the performance of the aerostatic bearing device [27, 28]. Generally the restrictors have different structures of narrow channels which is used for stabilizing air pressure to obtain different load capacity and stiffness of the air lm. Two of the most common restrictors, i.e., the inherent orifice restrictor and the simple orifice restrictor, are shown in Fig. 5. It can be seen that the difference between the two structures is the throttling area, which means the minimum cross section of the air flow channel. As shown in Fig 5(a), the throttling

Figure 5. Structure of two ori ce restrictors: (a) inherent ori ce restrictor and (b) simple ori ce restrictor. (p_0 : pressure at the ori ce inlet, p_d : pressure at the ori ce outlet, d : diameter of the ori ce, d_1 : diameter of the air cavity, h : thickness of the air lm, h_1 : height of the air cavity, h_2 : length of the ori ce.)

area of the inherent ori ce restrictor refers to an annular surface at the outlet of the ori ce. The air lm thickness h is the height of the annular surface. If the air lm thickness changes, the throttling area of the inherent ori ce will change at the same time. Thus the the load capacity and sti ness of the air lm will be unstable. It can be seen that the throttling area of the simple ori ce restrictor is the cross section of the ori ce as shown in Fig 5(b). The load capacity and sti ness of the air lm stay stable since the throttling area will not change along with the air lm thickness. In order to keep the simple ori ce characteristic, the ori ce cross section should be guaranteed as the minimum area of the air channel. To this end, an air cavity need to be constructed at the outlet of the ori ce. The parameters of the restrictor need to meet the following requirements

$$d_1 h > \frac{d^2}{4} ; \quad (1)$$

$$d(h_1 + h) > \frac{d^2}{4} ; \quad (2)$$

where d_1 and h_1 are the diameter and the height of the air cavity and d is the diameter of the ori ce. (1) and (2) can be written as

$$d_1 > \frac{d^2}{4h} ; \quad (3)$$

$$h_1 > \frac{d}{4} - h ; \quad (4)$$

Overall, the simple ori ce restrictor can be obtain under the satis ed conditions (3) and (4).

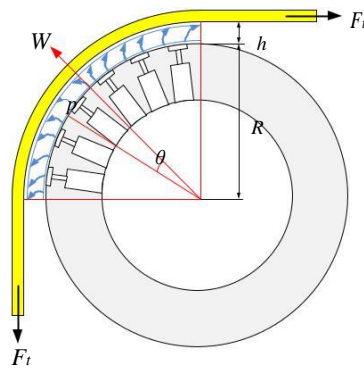

Figure 6. Working principle of the aerostatic bearing device

3. Modeling and analysis

3.1. Load capacity consideration

The load capacity is a key factor to the performance of the aerostatic bearing device. In order to support the web, the relationship between the web tension and the load capacity should be analysed. Fig. 6 shows the working principle of the aerostatic bearing device. It can be seen that an air film is generated to separate the static roller and the web. The load capacity of the air film W can be derived as follows

$$W = 2 \int_0^Z \int_0^L p r \cos \theta dx dz \quad (5)$$

where p is the pressure at the surface of the web; r is equal to the sum of R and h ; R is the radius of the cylindrical sleeve and h is the thickness of the generated air film; L is the length of the air film in cross direction.

Since the web has a thin thickness and low density, the weight of the web can be negligible. According to the force balance analysis, the relationship between the load capacity and the web tension F_t can be given as follows

$$W - 2F_t = 0 \quad (6)$$

Considering (5) and (6), the relationship between the web tension and the air pressure can be derived as

$$F_t = \int_0^Z \int_0^L p 2(R+h) \cos \theta dx dz \quad (7)$$

3.2. Mathematical model of the air film

The law of conservation of mass in the aerostatic lubrication can be described as: the increased mass of the gas control micro unit equals the net mass of the fluid flowing into the micro unit in the same time [29]. Based on the continuity equation, it can be derived as

$$\frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} + \frac{\partial(\rho w)}{\partial z} = \frac{\partial \rho}{\partial t}; \quad (8)$$

where ρ is the density of the micro unit, t is the time and u, v, w are the velocities in three directions.

The compressed air provided by the external gas source flows into the air film clearance through the restrictors, and then flows out through the boundary of the web. The entire process can be regarded as isothermal and derived by the state equation as

$$\frac{p}{\rho} = \frac{p_a}{\rho_a}; \quad (9)$$

where p_a and ρ_a are the pressure and density of the atmosphere.

The pressure distribution of the air flow field can be derived by adopting the Navier-Stokes equations. The Navier-Stokes equations are a series of equations to explain the basic flow laws of the viscous fluid which can be given as follows [30, 31].

$$\frac{\partial u}{\partial t} + (u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z}) = f_x - \frac{\partial p}{\partial x} + \mu (\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}) + \rho (\text{div} \mathbf{v}) \quad (10)$$

$$\frac{\partial v}{\partial t} + (u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z}) = f_y - \frac{\partial p}{\partial y} + \mu (\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2}) + \rho (\text{div} \mathbf{v}) \quad (11)$$

$$\frac{\partial w}{\partial t} + (u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z}) = f_z - \frac{\partial p}{\partial z} + \mu (\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} + \frac{\partial^2 w}{\partial z^2}) + \rho (\text{div} \mathbf{v}) \quad (12)$$

In order to simplify the Navier-Stokes equations, they can be transferred to dimensionless equations and the dimensionless items can be given as $u = V \bar{u}$; $v = (l/h_m)v = V \bar{v}$; $w = V \bar{w}$; $x = lx$; $y = h_m \bar{y}$; $z = bz$; $(b=l)$, where V is the characteristic velocity, h_m is the reference quantity of the air film, l and b is the characteristic length of the roller in the x and z direction. Moreover, $\bar{p} = \frac{p - p_0}{\rho_0 l^2}$; $\bar{t} = \frac{t}{l=V}$; $\bar{\mu} = \frac{\mu}{\rho_0 l^2}$. The Reynolds number is given as $Re = \frac{V h_m}{\mu}$, where $\rho_0, l=V$ are the characteristic quantities of viscosity coefficient, air pressure and time, respectively. Based on above relationships, the Navier-Stokes equation can be derived as

$$Re \left(\frac{\partial \bar{u}}{\partial \bar{x}} + \bar{u} \frac{\partial \bar{u}}{\partial \bar{x}} + \bar{v} \frac{\partial \bar{u}}{\partial \bar{y}} + \bar{w} \frac{\partial \bar{u}}{\partial \bar{z}} \right) = \frac{\partial \bar{p}}{\partial \bar{x}} + 2 \frac{\partial^2 \bar{u}}{\partial \bar{x}^2} + \frac{\partial^2 \bar{u}}{\partial \bar{y}^2} + \frac{\partial^2 \bar{u}}{\partial \bar{z}^2} + \rho (\text{div} \mathbf{v}) \quad (13)$$

1
0

$$\text{Re} \left(\frac{\partial \bar{v}}{\partial t} + \bar{u} \frac{\partial \bar{v}}{\partial x} + \bar{v} \frac{\partial \bar{v}}{\partial y} + \bar{w} \frac{\partial \bar{v}}{\partial z} \right) = \frac{\rho_0 h m^2}{\mu} \frac{\partial p}{\partial y} + 2 \frac{\partial \bar{v}}{\partial y} \left(\frac{\partial \bar{u}}{\partial y} \right) + \frac{\partial \bar{u}}{\partial x} \left(\frac{\partial \bar{u}}{\partial y} \right) + \frac{\partial \bar{v}}{\partial x} \left(\frac{\partial \bar{u}}{\partial x} \right) - \frac{1}{2} \frac{\partial \bar{w}}{\partial z} \left(\frac{\partial \bar{v}}{\partial z} \right) + \frac{1}{2} \frac{\partial \bar{w}}{\partial z} \left(\frac{\partial \bar{w}}{\partial z} \right); \quad (14)$$

$$\text{Re} \left(\frac{\partial \bar{w}}{\partial t} + \bar{u} \frac{\partial \bar{w}}{\partial x} + \bar{v} \frac{\partial \bar{w}}{\partial y} + \bar{w} \frac{\partial \bar{w}}{\partial z} \right) = \frac{\rho_0 h m^2}{\mu} \frac{\partial p}{\partial z} + 2 \frac{\partial \bar{w}}{\partial z} \left(\frac{\partial \bar{u}}{\partial z} \right) + \frac{\partial \bar{u}}{\partial x} \left(\frac{\partial \bar{u}}{\partial z} \right) + \frac{\partial \bar{v}}{\partial x} \left(\frac{\partial \bar{u}}{\partial x} \right) + \frac{\partial \bar{w}}{\partial z} \left(\frac{\partial \bar{v}}{\partial z} \right) + \frac{1}{2} \frac{\partial \bar{w}}{\partial z} \left(\frac{\partial \bar{w}}{\partial z} \right); \quad (15)$$

Considering that the thickness of the air film h is much lower than the roller's characteristic length l which can be defined by the width of the web L or the radius of the roller R . In most cases, $h = 10^{-4} - 10^{-3}$. Based on this consideration, any item that contains h^2 , Re , 2Re is relatively small dimensionless item, which can be omitted. Therefore, the inertia term in the Navier-Stokes equations can be removed. Considering above facts, the simplified Navier-Stokes equations can be derived as

$$\frac{\partial p}{\partial x} = \mu \left(\frac{\partial^2 u}{\partial y^2} \right); \quad (16)$$

$$\frac{\partial p}{\partial y} = 0; \quad (17)$$

$$\frac{\partial p}{\partial z} = \mu \left(\frac{\partial^2 w}{\partial y^2} \right); \quad (18)$$

where μ is the viscosity coefficient of air and the velocity boundary conditions of the air flow field can be given as $u = u_1, v = 0, w = w_1$, when $y = 0$; $u = 0, v = 0, w = 0$, when $y = h$. Integrating (18)-(20) twice with respect to y , the velocity distribution can be derived as

$$u = \frac{1}{2} \frac{\partial p}{\partial x} (y^2 - hy) + \frac{u_1}{h} (h - y); \quad (19)$$

$$w = \frac{1}{2} \frac{\partial p}{\partial z} (y^2 - hy) + \frac{w_1}{h} (h - y); \quad (20)$$

$$2 \frac{\partial^2 \psi}{\partial z^2} + \frac{\partial \psi}{\partial x} = 0$$

Integrating (8) with respect to y , leads to

$$\frac{\partial^2 \psi}{\partial z^2} + \frac{\partial \psi}{\partial x} = 0 \quad (21)$$

Substituting (9) (21) (22) into (23) and solving the integral, the motion equation of the air flow field is derived as

$$\frac{\partial}{\partial x} (h^3 p \frac{\partial u}{\partial x}) + \frac{\partial}{\partial z} (h^3 p \frac{\partial w}{\partial z}) = 12 \frac{\partial}{\partial t} (\frac{\partial \phi}{\partial x}) + 6 u_1 \frac{\partial}{\partial x} (\frac{\partial \phi}{\partial x}) + 6 w_1 \frac{\partial}{\partial z} (\frac{\partial \phi}{\partial z}) \quad (22)$$

Discretizing the equations (16) (17) (18) (22) based on finite volume method, the generated characteristic equations can be calculated to solve fluid flow problems by numerical calculation software in computer.[32, 33].

4. CFD simulations of the air flow field

In order to establish the numerical model of the flow field to study the property of the air film, the computer fluid dynamics (CFD) simulation is conducted. By defining the property of the fluids and the various boundary conditions, the numerical calculation is performed by high-performance computer. For the sake of obtaining the air pressure distribution of the air flow field to calculate the load capacity and stiffness, the commercial CFD software FLUENT 14.5 is adopted. Gambit 2.4.6 is adopted as the pre-processor to construct and mesh the 3D structure of the air flow field. The air film is expanded and modeled as shown in Fig.7. Fig. 7(a) shows the mesh model of the air flow field and Fig. 7(b) explains its boundary condition settings. A minimum restrictor array is uniformly distributed in the air flow field, where m denotes the quantity of the restrictors in cross direction, and n denotes the quantity of the restrictors in machine direction respectively. The structure parameters of aerostatic bearing device are illustrated in Table I. The material of the substrate web is selected as polyethylene terephthalate (PET) plastic with its property given in Table II. In order to optimize the structure of the aerostatic bearing device, the quantity of the restrictor and the diameter of the orifice are varied based on the simulation results.

Table 1. Parameters of the Aerostatic Bearing Device

Parameters	Value
Radius of the cylindrical sleeve (R)	50 mm
Width of the flexible web (L)	200 mm
Diameter of the air cavity (d_1)	3 mm
Height of the air cavity (h_1)	0.16 mm
Depth of the orifice (h_2)	1 mm
Number of restrictors in axial direction (m)	20
Air supply pressure (p_0)	0.025 Mpa

4.1. Structure modeling of the air flow field

According to the symmetry of the air flow field, the mesh model of only a quarter of the air flow field is constructed to reduce amount of calculation as shown in Fig. 7(a). Fig.

Figure 7. 3D model of the expanded ow eld: (a) mesh model and (b) boundary conditions.

Table 2. Material Properties of the PET Web

Properties	Value
Density ()	1.42 g/mm ³
Young's modulus (E)	2.96 Gpa
Tensile strength (b)	57.3 Mpa
Poisson ratio (v)	0.37
Thickness	50 m

7(b) shows the boundary conditions for the CFD analysis. Generally, the higher mesh density divided, the more accurate the results obtained. Therefore, the mesh should be divided as dense as possible. However, the geometric size of the ow eld spans large. The length and width of the ow eld are as large as tens of millimeters, while the thickness of the air lm is as small as several microns. Thus, it is di cult to divided a dense mesh. If the mesh is too loose, the CFD simulation would not get convergent solution due to iteration error. The CFD simulation in this article selects di erent kinds of meshes based on the size of the ow eld in di erent directions. Moreover, the mesh at the ori ces boundary is more dense. Based on these methods, the CFD simulations can get accurate convergent solution as much as possible. Moreover, it can be seen that the curvature of the air lm is ignored, the ow eld is spreaded as a plane with the same height to generate high quality mesh structure.

The width of the air ow eld B is given as

$$B = \frac{R}{2} : \quad (23)$$

In order to simplify the load capacity calculation, the air ow eld can be divided into n areas according to the row quantity of the restrictors in the machine direction.

It can be concluded that the pressure distribution in vertical direction of the air flow is invariable according to (10)-(12). According to the above conclusion, the load capacity of the i -th area can be derived as

$$F_i = 2 \int_0^{\frac{4n}{\sin \alpha}} p_i L(R + h) \cos \alpha \, dZ; \quad (24)$$

where p_i is the average pressure of the i -th area. The load capacity of the entire air flow can be calculated as

$$W = 2 \sin \alpha \sum_{i=1}^n \bar{X}_i L(R + h) p_i \cos \alpha; \quad (25)$$

The static stiffness K_W of the air flow can be given as

$$K_w = \frac{W(h + \Delta h) - W(h)}{\Delta h}; \quad (26)$$

where Δh represents the change of the air film thickness.

4.2. Structure optimization of the arrayed restrictors

Different from the conventional aerostatic bearings which are regarded as rigid body, the PET web is exible. If the exible web cannot be supported by uniform pressure, the boundary conditions of the flow field will be unstable. Therefore the uniform pressure of the air flow field needs to be guaranteed. A CFD model of the flow field is generated and the pressure nephogram is shown in Fig. 8(a), where the air film height is 40 μ m, the number of the restrictor is 20 \times 10 and the diameter of the orifice is 0.3 mm. It can be seen that an obvious pressure drop appears at the edge of the air flow field. This pressure drop will decrease the stability of the boundary condition. In order to increase the air pressure at the edge, a round of additional restrictors are added. The pressure nephogram of the air flow field with the additional restrictors are shown in Fig. 8(b). It can be seen that the pressure drop at the border is significantly reduced compared with the pressure distribution in Fig. 8(a), forming the uniformity of the air flow field. As shown in figure. 9, the pressure distribution of the curve center section of the air film are given. Line-test1 represents the center section pressure distribution of the flow field without additional restrictors while line-test2 represents the pressure distribution of the center section of the flow field with additional restrictors. The increase of the pressure at the edge can be recognized with the additional restrictors.

Moreover, the CFD simulations of the single orifice near the boundary and in the center of the flow field are conducted, respectively. As shown in Fig. 10, the pressure nephograms of each condition are illustrated. The pressure at the inlet is set as 0.25 Mpa, the diameter of the orifice is 0.3 mm and the thickness of the air film is 40 μ m. Moreover, since the thickness of the air film is small compared with the size of the flow field, the distribution of the grid in the film thickness direction is denser. The viscous model is selected as realizable k - ϵ , the energy equation is on, and the fluid material is selected as air with ideal-gas density. The pressure-velocity coupling scheme is chosen as simple. The spatial discretization is set as follows: least squares cell based gradient,

standard pressure, second order upwind density and momentum, and rst order wind turbulent kinetic energy. According to the CFD simulations, it can be observed that the pressure distribution of the ori ce in the center is more uniform than the pressure distribution of the ori ce near the boundary. Therefore, the addition of a round of restrictors is necessary. Moreover, Fig. 10(c) shows the velocity vector of the air ow near the outlet of the ori ce. Turbulence occurs at the outlet of the ori ce, as well as the intersection of each ori ce in the arrayed restrictors ow eld. Therefore, it is di cult to calculate the pressure distribution of the ow eld analytically. Nevertheless, we can study the property of the whole ow eld by conduct CFD simulation of the whole air lm to calculate the load capacity and sti ness of the aerostatic bearing device to the web.

4.3. CFD simulation of load capacity and stiffness

The aerostatic bearing device is mainly evaluated by its load capacity and stiffness. In order to optimize the performance of the aerostatic bearing device, research should be done to study the influence of aerostatic bearing device structure parameters. Based on simple variable method, the structure parameters are varied to conduct repeated CFD simulation about the load capacity and stiffness of the air flow field. Finally, the variation curves of the load capacity and stiffness with respect to the thickness of the air film are plotted. Fig. 11 shows the curves when the quantity of the restrictor rows is set to 10 and the diameter of the orifice is varied, while Fig. 12 shows the curves when the diameter of the orifice is 0.3 mm and the number of the restrictor rows is varied.

According to the CFD simulation results the following conclusions can be given.

When the diameter of the orifice is increased, the load capacity of the aerostatic bearing device is higher. It is mainly resulted from the increase of the air pressure at the outlet of the orifice. However, the maximum stiffness of the flow field is significantly decreased. Therefore it can be concluded that smaller diameter of the orifice resulting in lower load capacity and higher stiffness. However, processing difficulty will be greatly increased when the diameter of the orifice is too small. Meanwhile the cleanliness of the air source will be tougher to prevent the impurities in air from blocking the restrictor.

When the number of the restrictors is increased, the load capacity of the air flow field is higher while the maximum stiffness is lower. However, once the the number of the restrictors is up to a sufficient extent, it has little effect on the load capacity

and stiffness of the air flow field as shown in Fig. 11. Therefore, if the uniformity of air flow field can be ensured, the number of the restrictors should be restricted since larger quantity of restrictors leads to higher manufacturing difficulty and greater expense.

Figure 12. A action of the quantity of the restrictor rows on (a) load capacity and (b) stiffness.

5. Experimental tests

Experimental tests are carried out to investigate the performance of the aerostatic bearing system. A 20 \times 10 restrictor array at 0.2 mm diameter is distributed on the surface of the aerostatic bearing device. The left parameters of the device is the same as used in the CFD simulation shown in Table I.

5.1. Tension control strategy

The web tension should be kept at a constant in the printing process. Inappropriate tension will influence the transport stability and the printing quality. The web would be deformed or ruptured if the tension is too high. While a slide or wrinkles would appear if the tension is too low.

Figure.13 shows the schematic diagram of the tension control system. Servo motor 1 works at the torque model while servo motor 2 works at the velocity model to set the tension and velocity of the web, respectively. In order to keep the web tension and velocity constant, the resistance torque and rotating speed of the servo motors should change along the variation of the web reel diameter. Two laser sensors are employed to measure the diameter. The tension detector will detect the load on the idler roller generated by the web tension. When the actual tension deviates from the predetermined value, the resistance torque of servo motor 1 should be revised through specific control algorithms. Besides, the spring tension adjustment mechanism is used to compensate the tension fluctuation passively.

As shown in Fig.14, the tension variation is detected by the pressure sensor. The web velocity is set at 30 mm/s. The tension fluctuation is controlled within 1 N.

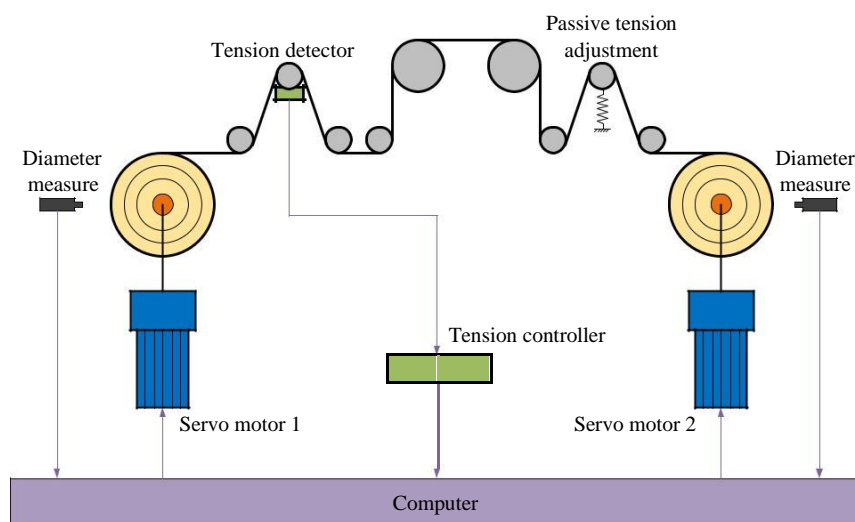

Figure 13. Schematic of the tension control system.

5.2. Performance test of the aerostatic bearing system

Experimental tests are carried out to investigate the performance of the aerostatic bearing system. A high precision laser sensor is adopted to detect the gap height and vibration performance of the web. The environmental noise of the laser sensor is measured as shown in Fig. 15, and it can be seen that the noise is about 0.1 m.

Once the variation of the air film thickness along the web tension is obtained, the load capacity and the stiffness of the air film can be calculated. The comparison

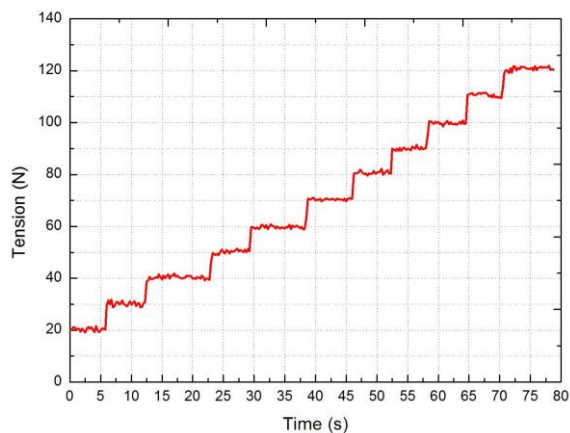

Figure 14. Tension control experiment.

Figure 15. Environment noise of the laser sensor.

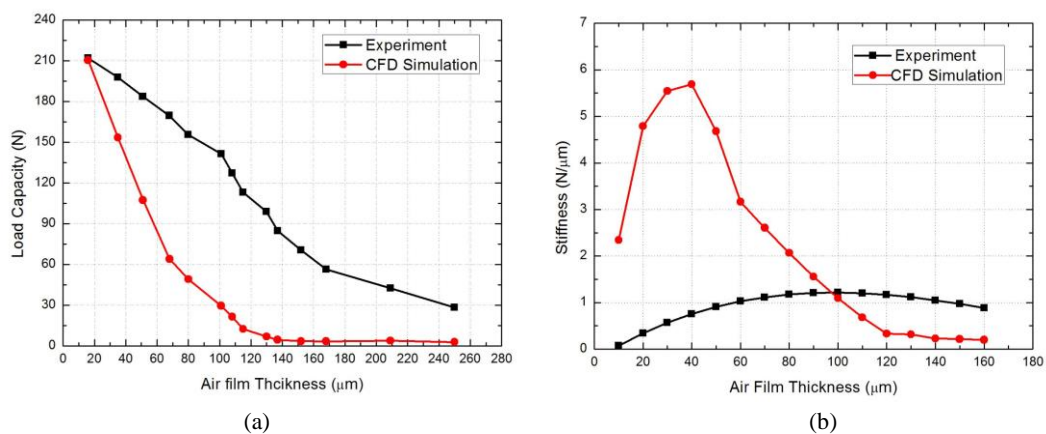

Figure 16. Comparison between the experiment and the CFD simulation: (a) load capacity comparison and (b) stiffness comparison.

between the experimental results and the CFD simulation are shown in Fig. 16. Due to the restriction of friction between the the mechanical expansion shaft and the web reel, the tension of the web cannot be as large as the CFD condition. Therefore the web tension is set from 20 N to 150 N. The load capacity is varied from 28.28 N to 212.13 N according to equation (6). Moreover, the load capacity is measured from 20 m of the air lm thickness. The sti ness curve is derived from the load capacity curve according to Eq. (26).

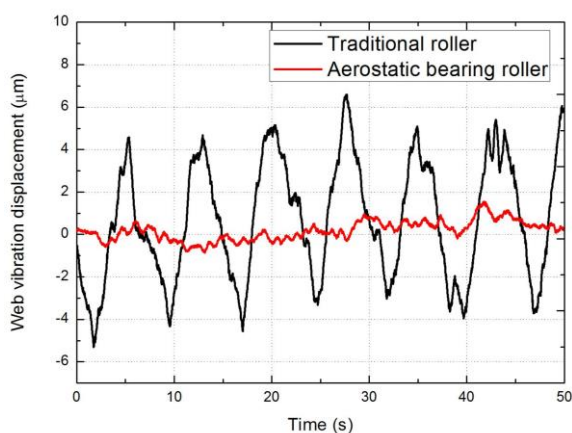

Figure 17. Web vibration comparison between the traditional roller and aerostatic bearing roller.

From the comparison chart shown in Fig 16, the following conclusions can be obtained. According to the experimental results, the CFD simulation results can reflect the trend of the load capacity and sti ness. The load capacity of the air lm decreases as the increase of the air lm thickness. The air lm sti ness has a maximum value at a particular value of the air lm thickness. Signi cant numerical di erences exist in the comparison between the CFD simulation and the experimental results. As the air lm thickness increases, the actual load capacity decreases is relatively slowly compared to the CFD simulation. The actual air lm sti ness is far below the CFD simulation value. The reasons for the di erences will be discussed later.

When the web tension is low, the thickness of the air lm would be relatively thick, resulting in a low sti ness of the air lm. The external disturbances will interfere the position accuracy of the web. Due to the exibility of the web, the air ow will cause vibration of the web at the low tension condition. Therefore the work tension of the web should be controlled strictly. When the web tension is relatively high, the position error of the web is eliminated e ectively. The deviation displacement of the web in the vertical direction will be detected to compare with the position accuracy achieved by di erent transport methods. The laser sensor detects the position uctuations of the web at the aerostatic bearing area and the traditional rolling roller, respectively. The web tension is controlled at 150 N, and the web velocity is at 20 mm/s. As shown in Fig. 17, the comparison chart shows the e ectiveness of the aerostatic bearing roller.

Due to the machining and assembly errors, dynamic position error of the web on the rolling roller is detected which is about 6 m. While the position error of web at the aerostatic bearing area is about 1 m. Comparing to the traditional web transport method, a much better dynamic performance is obtained with the proposed aerostatic bearing method.

5.3. Discussion

The deviation of experimental results from the CFD simulation results arises from complex reasons as follows.

The exible web is regarded as a rigid body in the CFD boundary condition setting. In the experiment situation, when the web tension is high enough, the web can be regard as a rigid body. While at a low tension condition, the web cannot maintain the uniform plate structure because of the air lm stress concentration caused by the restrictor array.

The pressure distribution would be uneven when the air lm thickness becomes thicker, resulting in non-uniform supporting forces. From the observation of the experiments, the web would appear severe vibration at low tension. To obtain stable aerostatic bearing performance, the tension should be precisely controlled.

During the experimental process, the web is constantly moving. In the CFD simulation condition, the web motion is ignored. This may lead to changes in the boundary conditions.

Maintaining a stable aerostatic bearing status of the exible web needs strict conditions. Improper experimental parameter settings will lead to non-ideal experimental phenomena. For the proposed aerostatic bearing system, the tension should be set at least higher than 120 N to obtain high rigidity of the exible web. When the web is transported into the aerostatic bearing area, the cross direction error should be eliminated to guarantee the symmetry boundary condition of the ow eld. The web guide module to control the web position in the cross direction need to be introduced in the future work.

Although there is some deviation between the CFD simulation results and the experimental results, but the CFD simulation is still able to re ect the relationship between the load capacity, sti nness and the air lm thickness, which can provide theoretical support for the design of the aerostatic bearing system.

6. Conclusion

The study of the roll-to-roll printed electronics has raised a tough task to design precision transport equipment to guarantee the position accuracy of the web. To this end, a novel aerostatic bearing system is pesented in this paper. Design, analysis, and characterization of the aerostatic bearing system are proposed. The core part of the R2R

system is a pair of aerostatic bearing devices with arrayed restrictors. The aerostatic bearing device can generate a layer of air film between the web and the roller to eliminate the adverse impact of the traditional roller with both support and transport uses. The conception design of the device is presented and the theoretical model of the airflow field are established. CFD numerical simulations are developed to evaluate and optimize the property of the device. Finally, a roll-to-roll prototype is built to experimentally investigate the performance of the aerostatic bearing roller. Experimental results have proved the feasibility of the proposed aerostatic bearing method. By adopting the aerostatic bearing roller, the position accuracy in the vertical direction of the web can be achieved to 1 μm , which is significantly better than the traditional method.

Precise tension control and cross direction error compensation are necessary for further improving the performance of the aerostatic bearing system. In the future work, an active tension adjuster and a web guide module will be developed to enhance the tension control precision and the web position accuracy. In order to further investigate the aerostatic bearing method, different kinds of air bearing, such as the porous bearing will be investigated to fabricate the air bearing roller. Specific air pressure sensors will be mounted on the aerostatic bearing device to detect the air pressure in different position of the airflow field. Moreover, a complete set of roll-to-roll inkjet printing system will be built to conduct the multi-layer printing experiment.
