Epitaxial strain and electric boundary condition effects on the structural and ferroelectric properties of BiFeO₃ films

 Florian Johann,* Alessio Morelli, Daniel Biggemann, Miryam Arredondo, and Ionela Vrejoiu Max Planck Institute of Microstructure Physics, Weinberg 2, D-06120 Halle, Germany
(Received 17 May 2011; revised manuscript received 22 August 2011; published 19 September 2011)

The influence of both compressive and tensile epitaxial strain along with the electrical boundary conditions on the ferroelastic and ferroelectric domain patterns of bismuth ferrite films was studied. BiFeO₃ films were grown on SrTiO₃(001), DyScO₃(110), GdScO₃(110), and SmScO₃(110) substrates to investigate the effect of room temperature in-plane strain ranging from -1.4% to +0.75%. Piezoresponse force microscopy, transmission electron microscopy, x-ray diffraction measurements, and ferroelectric polarization measurements were performed to study the properties of the films. We show that BiFeO₃ films with and without SrRuO₃ bottom electrode have different growth mechanisms and that in both cases reduction of the domain variants is possible. Without SrRuO₃, stripe domains with reduced variants are formed on all rare earth scandate substrates because of their monoclinic symmetry. In addition, tensile strained films exhibit a rotation of the unit cell with increasing film thickness. On the other side, the presence of SrRuO₃ promotes step flow growth of BiFeO₃. In case of vicinal SrTiO₃ and DyScO₃ substrates with high quality SrRuO₃ bottom electrode and a low miscut angle of $\approx 0.15^{\circ}$ we observed suppression of the formation of certain domain variants. The quite large in-plane misfit of SrRuO₃ with GdScO₃ and SmScO₃ prevents the growth of high quality SrRuO₃ films and subsequent domain variants reduction in BiFeO₃ on these substrates, when SrRuO₃ is used as a bottom electrode.

I. INTRODUCTION

Multiferroic materials stimulated a great deal of investigations because of their potential coupling between electric and magnetic order parameters, making them interesting for both fundamental research and applications.^{1,2} Bismuth ferrite (BiFeO₃) is a very promising multiferroic, being ferroelectric and antiferromagnetic at room temperature.³ BiFeO₃ is a rhombohedrally distorted perovskite with a room temperature pseudocubic lattice constant $a_c = 3.96$ Å and a distortion angle $\alpha = 0.6^{\circ}.^4$ It has a high ferroelectric polarization of $\approx 100 \ \mu C/cm^2$ along the polar [111] direction. For $(001)_c$ oriented epitaxial BiFeO₃ films eight possible ferroelectric variants can occur, corresponding to four different ferroelastic variants, as depicted in Fig. 1. Streiffer et al.⁵ predicted that rhombohedral ferroelectric films may form complex stripe domain patterns with both {100} and {101} twin boundaries as a result of this numerousness of polarization directions. In consequence, it is complicated to control the occurrence of particular domain variants.⁶ Furthermore, the existence of many domain variants can suppress the ferroelectric properties of BiFeO₃.⁷ Several publications reported on selection of certain domain variants by reducing the substrate symmetry, either by introduction of a high miscut angle on cubic $SrTiO_3(001)^8$ or by the use of orthorhombic (110)-cut rare earth scandate substrates.⁹ The rare earth scandates have a GdFeO₃-like structure,¹⁰ where in one orthorhombic unit cell four monoclinic distorted perovskite pseudocubes are merged [Fig. 1(c)]. For $(110)_o$ oriented substrates, two slightly different pseudocubic in-plane parameters occur, which are listed in Table I together with the monoclinic distortion angle β , for DyScO₃, GdScO₃, and SmScO₃. As sketched in Fig. 1(c), for these kind of substrates we make the assignment of the orthorhombic $[001]_{\rho}$ axis as pseudocubic $[100]_{c}$ axis and the $[1\overline{1}0]_o$ axis as $[010]_c$, where o and c stand for the orthorhombic and cubic notation, respectively.

Chu *et al.*¹² reported the formation of quasi-onedimensional stripe domain patterns in BiFeO₃ films deposited on DyScO₃(110), promoted by careful control of the thickness and growth mode of the SrRuO₃ bottom electrode. The same kind of stripe domain pattern was, however, seen for BiFeO₃ films grown directly on DyScO₃(110) and TbScO₃(110), and was attributed to the two different in-plane lattice constants of the orthorhombic substrates.^{9,13,14} Recently tensile strained BiFeO₃ has been devoted a great deal of theoretical investigations,¹⁵ however there are not many experimental studies to provide data to be compared with the theoretical predictions. In particular there are no reports about tensile strained BiFeO₃ films investigating the domain patterns.

We report on the structural properties, domain patterns, and ferroelectric properties of epitaxial BiFeO₃ films grown by pulsed laser deposition on SrTiO₃(001), DyScO₃(110), GdScO₃(110), and SmScO₃(110). With these substrates the effect of an in-plane epitaxial strain ranging from -1.4% to +0.75% on BiFeO₃ films could be investigated.

We found that the symmetry of the substrate and the electrical properties of the bottom interface have a more evident influence on the domain variants than the magnitude and sign of the epitaxial strain. For BiFeO₃ films grown directly on the substrate, we observed that: (i) Under tensile stress, BiFeO₃ grown on the rare earth scandates exhibit stripe domains with reduced structural variants as reported for compressive stress,^{9,13} but with much finer stripe widths, down to 10 nm. Our investigations suggest that the origin of the variant selection is rather the monoclinic nature of the substrate than the two different in-plane lattice constants, or at least a combination of both. (ii) An additional effect of tensile strain is that, with increasing thickness, the films show a slight rotation of the pseudocubic unit cell.

The situation is different when a $SrRuO_3$ bottom electrode was employed, because of its additional structural and electrical properties: (i) BiFeO₃ films on $SrRuO_3/DyScO_3(110)_o$ and

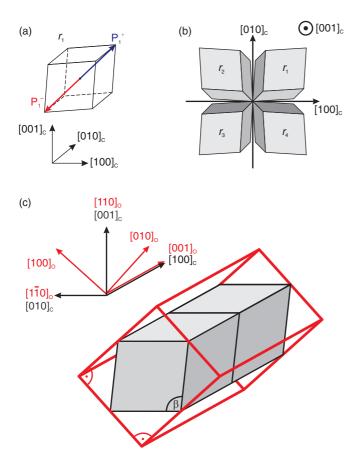

FIG. 1. (Color online) (a) The BiFeO₃ perovskite cube is distorted along the direction of polarization. For one distortion two directions for the ferroelectric polarization are possible, shown for variant r_1 . (b) All possible structural variants r_1 , r_2 , r_3 , and r_4 , viewed from the top of an epitaxial (001)_c-orientated BiFeO₃ film. (c) Structure of the rare earth scandates with the orthorhombic unit cell in red and two of the four pseudocubic perovskite cells inside the orthorhombic unit cell in black. The pseudocubes are monoclinic distorted with an angle β .

as well on low miscut $SrRuO_3/SrTiO_3(001)_c$ substrates exhibit a reduced number of domain variants due to the electrical properties of $SrRuO_3$ and the miscut direction of the substrate. (ii) In case of $GdScO_3$ and $SmScO_3$ the lattice mismatch of $SrRuO_3$ with these substrates is very high, resulting in a worse film quality and partial strain relaxation. Hence, for

TABLE I. (Pseudo)cubic in-plane lattice constants a_c and b_c along $([010]_c \parallel [\bar{1}10]_o)$ and $([100]_c \parallel [001]_o)$, respectively, as well as the monoclinic angle β of the used substrates and (averaged) in-plane lattice misfit with BiFeO₃ and SrRuO₃. Values for rare earth scandate lattice constants were taken from Ref. 11.

				Misfit with	
	a_c (Å)	b_c (Å)	β (deg)	BiFeO ₃	SrRuO ₃

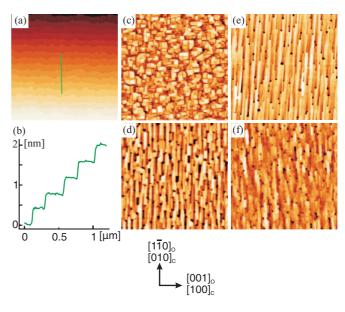

FIG. 2. (Color online) AFM topography of (a) GdScO₃(110) substrate with corresponding scan line in (b). AFM surface morphology of 26 nm thick BiFeO₃ films grown on (c) SrTiO₃(001) (scale: 9 nm, rms: 2.0 nm), (d) DyScO₃(110) (scale: 11 nm, rms: 2.7 nm), (e) GdScO₃(110) (scale: 4 nm, rms: 1.0 nm), and (f) SmScO₃(110) (scale: 7 nm, rms: 1.7 nm). All images are $4 \times 4 \mu m^2$.

BiFeO₃ films grown on either GdScO₃ or SmScO₃ with bottom SrRuO₃ electrodes, no preferred domain variants could be observed.

Overall, our investigations show that the properties of $BiFeO_3$ films are very sensitive to growth mode, the type of bottom interface, the substrate symmetry and epitaxial strain conditions.

II. EXPERIMENT

BiFeO₃ films were grown by pulsed laser deposition on $SrTiO_3(001)_c$, $DyScO_3(110)_o$, $GdScO_3(110)_o$, and $SmScO_3(110)_a$ with and without $SrRuO_3$ bottom electrode. All substrates had a miscut of 0.1° to 0.15° toward $[010]_{c}$. SrTiO₃ was prepared by an etching and annealing step as reported in Ref. 16, whereas DyScO₃, GdScO₃, and SmScO₃ were just annealed for 2 h at 975, 1100, and 1200 °C, respectively. All substrates had uniform, atomically flat terraces of ≈ 200 nm in width and step heights of one unit cell after preparation. After optimizing the growth conditions, SrRuO₃ and BiFeO₃ films were deposited at $650 \,^{\circ}$ C in an O₂ pressure of 0.14 mbar. The BiFeO₃ films were ablated from stoichiometric targets with a laser fluence of around 0.5 J/cm² and a laser repetition rate of 5 Hz, which resulted in a growth rate of ≈ 1 nm/min. The deposited films were cooled down to room temperature in 200 mbar partial pressure of oxygen with 900 °C/h. BiFeO₃ films of about 13, 26, and 38 nm in thickness were deposited directly on the substrates and about 30 nm thick BiFeO₃ films were grown on substrates with SrRuO₃ bottom electrode. For this thickness the BiFeO₃ film is still fully strained.¹⁷ We varied the SrRuO₃ thickness from 5 to 50 nm, depending on the extent of misfit of SrRuO₃ with the substrate.

The morphology of the substrates and films were measured with a commercial atomic force microscope (Veeco Digital Instruments D5000) in tapping mode. Piezoresponse force microscopy (PFM) was performed on a XE-100 Park System in contact mode to study the ferroelectric domains and the piezoelectric response of the films. Cantilever with spring constants of 2.8–7.5 N/m and tips coated with a conductive layer of Pt/Ti or Pt/Ir were used. In order to achieve 3D reconstruction of the polarization patterns vertical PFM (VPFM) and lateral PFM (LPFM) images were acquired with two different cantilever orientations.¹⁸ Plan-view and cross-section specimens for transmission electron microscopy (TEM) characterization were prepared by conventional techniques.¹⁹ Conventional TEM was performed on both type of samples on a Philips CM20T microscope at 200 kV. High resolution TEM (HRTEM) images were obtained from cross-section samples on a Jeol 4010 microscope with a LaB₆ electron gun, point resolution of 1.6 Å at 400 kV. X-ray diffraction (XRD) measurements were done with a Philips X'Pert system. The different structural variants of the BiFeO₃ films were studied with XRD reciprocal space maps (RSMs).^{20,21}

III. RESULTS AND DISCUSSION

Epitaxial BiFeO₃ films grown directly on the substrate and those grown on a SrRuO₃ bottom electrode layer show different properties. Most evident is the different growth mode of BiFeO₃ in the two cases as seen by AFM topography. If the BiFeO₃ film is grown directly on the substrate a 3D growth is observed (Fig. 2), whereas for SrRuO₃ bottom electrode the BiFeO₃ stays atomically flat (Fig. 8). The origin of this could be the different surface diffusivity of BiFeO₃ on the different surface terminations, which is in case of the substrates a B-site termination^{16,22} and in case of SrRuO₃ step-flow-grown layers an A-site termination.²³ Due to these major differences the two cases will be discussed separately, first the BiFeO₃ films grown directly on the substrates, followed by the BiFeO₃ films with SrRuO₃ bottom electrode.

A. BiFeO₃ films grown directly on the substrate

As an example of a prepared substrate morphology, Fig. 2(a) shows the topography of a vicinal GdScO₃(110) substrate and Fig. 2(b) shows its scan line across the terraces. For all films shown in Fig. 2 the orientation of the substrate terraces is as shown in Fig. 2(a). The morphology of the BiFeO₃ films grown without SrRuO₃ bottom electrode show square island in case of SrTiO₃ substrate [Fig. 2(c)] and elongated islands or stripes in case of rare earth scandates [Figs. 2(d)–2(f)]. The elongation is for all films on the three types of rare earth scandates aligned along the $[1\overline{10}]_o$ direction, which is the direction of higher in-plane misfit for BiFeO₃ with these substrates.

To investigate the ferroelectric domain structure, PFM measurements were performed on all samples, shown in Fig. 3. Measurements were carried out with two cantilever orientations: (A) aligned along $[010]_c$ and (B) aligned along $[100]_c$. In the VPFM images a dark (bright) contrast corresponds to a polarization pointing outward (inward) the sample surface, while for the LPFM images a black (white) contrast corresponds to a projection of the polarization pointing in

the sample plane to the right (left) side of the cantilever. As a result, for both LPFM contrasts two possible directions of polarization are possible, as depicted in the insets of the LPFM images. For all of the films the PFM measurements reveal that the surface morphology is related, to a certain extent, to the ferroelectric/ferroelastic domain patterns. The domain walls almost always match with topographic features for BiFeO₃ grown without SrRuO₃ bottom electrode.

For films deposited on SrTiO₃ the PFM images show similar patterns for both cantilever orientations, therefore only one orientation is shown here [Fig. 3(a)]. The VPFM images reveal that almost the complete film has a polarization pointing upward, with only some stripes pointing downward. The LPFM shows an evenly distributed contrast with domain boundaries matching the island borders seen in the topography image, suggesting that each island is monodomain. Furthermore, the bright stripes seen in the vertical PFM image are positioned at the domain walls seen in the lateral PFM. Combining both VPFM and LPFM images it can be concluded that mostly the four polarization directions pointing upward $(P_1^+, P_2^+, P_3^+,$ and P_4^+) occur with equal distribution. From this it follows that all four structural variants, r_1 to r_4 , occur in the BiFeO₃ film on SrTiO₃(001) equally.

Investigations of the films deposited on the orthorhombic rare earth scandates show different domain configuration than in case of films deposited on cubic SrTiO₃. PFM measurements reveal that the same kind of stripe domains with reduced domain variants appear for both compressive and tensile strain [Figs. 3(b)-3(d)], as reported for compressive strain.^{9,13} For the cantilever alignment (B), exactly the same stripe domain pattern is seen in both VPFM and LPFM images. Hence, it can be concluded that from the four structural variants [see Fig. 1(b)] only two occur, namely r_3 and r_4 . In case of a cantilever orientation (A) the VPFM domain pattern is similar, but the LPFM domain pattern changes to bigger domain sizes. Within such a domain, the stripes seen in VPFM have an alternating polarization of either P_3^+ and P_4^- or P_3^- and P_4^+ , both having 109° domain walls as sketched in Fig. 3(e). The domain walls seen in the LPFM image (A) are either 71°, if there is no corresponding domain wall visible in VPFM, or 180° domain walls otherwise.

On all three orthorhombic substrates the BiFeO₃ stripes with polarization pointing outward appear to be wider than the stripes pointing inward, presumably due to electric interactions at the interface with the highly insulating substrates. The stripe periodicity is \approx 140 nm in case of a DyScO₃ substrate, whereas on GdScO₃ and SmScO₃ substrates the stripes are much finer, some of them even with a width of less than 10 nm, which is the limit of lateral resolution for PFM.²⁴ As a result the PFM signal is very low and the domain shape can not be resolved in detail.

To circumvent the resolution limit of PFM we employed TEM to investigate the shape and size of the domains of BiFeO₃ films subjected to tensile epitaxial strain in more detail. Regarding TEM one is restricted to the investigation of different structural variants (the two different ferroelectric variants of one structural variant can not be visualized), but the lateral resolution is orders of magnitude higher compared to PFM. A plan-view specimen was prepared from a 26 nm thick BiFeO₃ film and a cross section specimen was prepared from

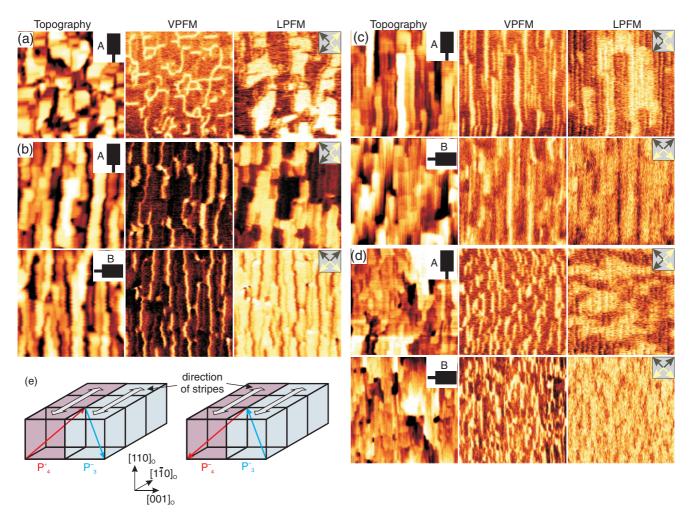

FIG. 3. (Color online) Topography, VPFM and LPFM images (left to right) of 26 nm thick BiFeO₃ films without SrRuO₃ bottom electrode on (a) SrTiO₃, (b) DyScO₃, (c) GdScO₃, and (d) SmScO₃. Samples were measured with the cantilever aligned along (A) $[010]_c$ and (B) $[100]_c$, as depicted in the inset in each topography image. The insets in the LPFM images show the two possible polarization directions for both contrasts. All images are $1 \times 1 \ \mu m^2$. (e) Schematic representation of domain configuration with 109° domain boundaries for BiFeO₃ films grown on rare earth scandates.

the 38 nm thick BiFeO₃, both grown on SmScO₃(110). As can be seen in Fig. 4(a), the stripe domains observed by plan-view TEM match in size with those seen by PFM. Most of the stripe domains end in a needle-like shape and merge alternating with $\pm 45^{\circ}$ with respect to the stripe direction. The averaged stripe width is 10–15 nm, but there are also domains which are less than 5 nm in width. The cross section TEM image in Fig. 4(b) shows both vertical domain walls, corresponding to the stripe domain walls, and 45° domain walls, corresponding to the needle like ending of the stripes. The HRTEM in Fig. 4(c) reveals a sharp interface and no misfit dislocations were visible with these measuring conditions.

Streiffer *et al.*⁵ predicted the formation of this kind of stripe domains for rhombohedrally distorted ferroelectrics. Because of symmetry reasons, four different pairs of twin domain patterns should occur: for domains with $\{010\}_c$ twin boundaries, the patterns r_1/r_2 and r_3/r_4 can exist, for domains with $\{100\}_c$ twin boundaries, the patterns r_2/r_3 and r_1/r_4 are possible (Fig. 2 in Ref. 5). In case of our BiFeO₃ films under compressive strain on cubic SrTiO₃, this mechanism does not seem to be the dominant one, but it is

the formation of monodomain islands. The films on the rare earth scandate substrates show one of the four possible twin patterns. The two different in-plane lattice constants of the (110)-cut substrates might reduce the four twin patterns to two, however the existence of only r_3/r_4 twin pattern cannot be explained by this due to symmetry reasons. To rule out the influence of the miscut direction, a BiFeO₃ film was grown on a SmScO₃(110) substrate with the miscut in the opposite direction, toward $[0\bar{1}0]_c$. Independent from the miscut direction the same structural domain variants r_3 and r_4 were formed in the film.

To further investigate the origin of the twin pattern selection and structural variants XRD-RSMs were carried out on all samples. In contrast to PFM and TEM, the XRD measurements allow us to analyze a larger area of the sample, and thus give macroscopic information on the structure of the film. For RSMs performed around $(203)_c$, $(\bar{2}03)_c$, $(023)_c$, and $(0\bar{2}3)_c$ reflections, the BiFeO₃ peak splits into two peaks, each peak corresponding to two different variants. For the $(203)_c/(\bar{2}03)_c$ peaks the x-ray diffraction plane is parallel to the $(010)_c$ plane and the variants split up into a r_1/r_4 peak and a r_2/r_3 peak. For

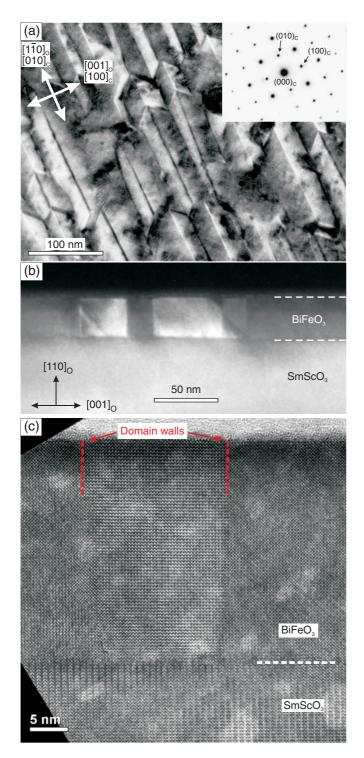

FIG. 4. (Color online) (a) Bright field plan-view TEM image along $[110]_o$ zone axis of a 26 nm BiFeO₃ grown on SmScO₃(110). (b) Dark field TEM cross section image of 38 nm thick BiFeO₃ film a few degrees out from $[1\overline{10}]_o$ zone axis to enhance the domain contrast and (c) HRTEM image showing two 109° domain boundaries in the BiFeO₃ film and interface with the SmScO₃ substrate.

RSM performed around $(023)_c$ or $(0\overline{2}3)_c$ the x-ray diffraction plane is parallel to $(100)_c$ and the two pairs r_1/r_2 and r_3/r_4 can be distinguished. The different RSMs were acquired by rotating the sample in steps of $\phi = 90^\circ$.

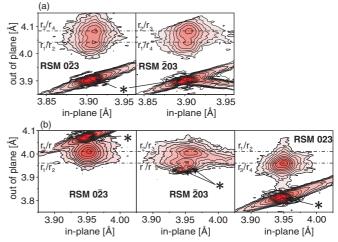

FIG. 5. (Color online) XRD RSMs for a film on (a) SrTiO₃(001) around $(0\bar{2}3)_c$ and $(\bar{2}03)_c$, as well as for a film on (b) DyScO₃(110) around $(0\bar{2}3)_c$, $(\bar{2}03)_c$, and $(023)_c$. The substrate peaks are labeled with (*). All maps are displayed in logarithmic color code.

As seen in Fig. 5(a) the film on SrTiO₃ shows a peak splitting for both RSMs, around $(0\bar{2}3)_c$ and $(\bar{2}03)_c$. This is in agreement with the PFM result that all four structural domains appear. In contrast, for the films on all of the rare earth scandates, peak splitting was observed only for some RSMs. Figure 5(b) displays the RSMs measured for BiFeO₃ on DyScO₃ substrate. For $(0\bar{2}3)_c$ and $(023)_c$, only one BiFeO₃ peak is visible, whereas for $(\bar{2}03)_c$ and $(203)_c$ the peak split is visible $[(\bar{2}03)_c$ is identical to $(203)_c$, and thus not shown]. In agreement with the PFM measurements [Fig. 3(b)], only the structural variants r_3 and r_4 occur in the BiFeO₃ film deposited on DyScO₃.

Due to the monoclinic structure of the substrate, the substrate peaks appear at different positions for the different RSMs. It can be seen from Fig. 5(b) that the BiFeO₃ peak for the RSMs around $(0\overline{2}3)_c$ and $(023)_c$ is close to the DyScO₃ peak, meaning that the film tries to adopt the direction of monoclinic distortion of the substrate as depicted in Fig. 6(a). Since the monoclinic distortion of the substrate is along one of the pseudocubic axes and the distortion for BiFeO₃ is along one of the diagonals of the pseudocube, there are two equally good possibilities for the BiFeO₃ cell to match the substrate distortion, namely by structural variants r_3 and r_4 . The origin of the selection of the r_3/r_4 stripe patterns seems to be a combination of both: the mechanism of coherent twin boundaries described by Streiffer et al.⁵ and of the preferred direction of distortion due to the monoclinic distorted substrate.

Furthermore, the BiFeO₃ films under tensile strain on GdScO₃ and SmScO₃ show a thickness dependent peak splitting in the RSM around $(203)_c$. The RSMs for films on SmScO₃ with thicknesses of 13, 26, and 38 nm are depicted in Fig. 7. The BiFeO₃ films on GdScO₃ display the same behavior, so the data is not shown here. The RSM data is shown in two representations, first $(\Theta - \omega)$ versus 2Θ and second transformed into lattice parameters *a* and *c*. In the first representation $(\Theta - \omega)$ gives the tilt of the planes under investigation with respect to the substrate surface $(001)_c$,

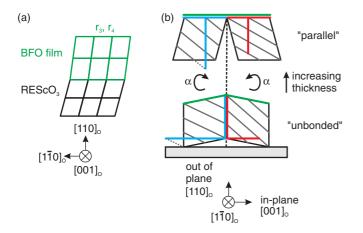

FIG. 6. (Color online) (a) An epitaxially strained BiFeO₃ film prefers a structural variant which adapts to the monoclinic distortion of the rare earth substrates. (b) Schematics of the rotation of the BiFeO₃ unit cell with thickness. $(203)_c$ planes (gray lines) and extracted in-plane and out-of-plane lattice constants shown for both structural variants (red and blue lines, respectively), leading to a transition from a vertical to a horizontal peak splitting in RSMs. Green line shows orientation of the $(004)_c$ plane in both cases.

whereas from the 2Θ value the plane spacing can be deduced. In the other case, from the calculated lattice parameters a and c the plane distances parallel to the sample surface and perpendicular to the sample surface can be derived, respectively. As seen in Figs. 7(a)-7(c), for all thicknesses the (203) plane spacing stays constant, but the planes seem to have different tilt angles with respect to the substrate surface. Starting with the 13 nm thick film, the additional layers from the two structural variants rotate in opposite directions. For the 38 nm thick sample, the planes form reflections with maximal intensity at different positions with respect to the thinner films. The different orientation of the first layers is, however, still visible as a tail. The 26 nm thick BiFeO₃ film is close to the transition with no pronounced peak reflection at none of the two positions [Figs. 7(b) and 7(e)]. On the other hand, when converted into lattice constants, with increasing film thickness there is a transition from a horizontal splitting into a vertical splitting. This means that the first BiFeO₃ layers for both structural variants have the same $(203)_c$ plane spacing projected on the out of plane direction, in contrast to the layers thicker than ≈ 26 nm, which have the same $(203)_c$ plane spacing projected on the in-plane direction. A possible explanation is a rotation of the unit cell as depicted in Fig. 6(b). Starting from an unbonded configuration with the substrate surface, the unit cell rotates with increasing thickness to a parallel alignment with the substrate surface. For a further information RSMs around $(004)_c$ were performed. The unbonded case should show a peak splitting due to the two different plane orientations, whereas in the parallel case only one peak is expected [Fig. 6(b)]. As can be seen in Figs. 7(g) and 7(h) the measurements are in agreement with this consideration. A further evidence is the amount of rotation α of 0.3° to 0.4° which exactly match with the rhombohedral distortion of BiFeO₃ projected onto the $(010)_c$ plane, which is seen by these XRD measurements. This rotation might be one possible way to relax part of the strain.

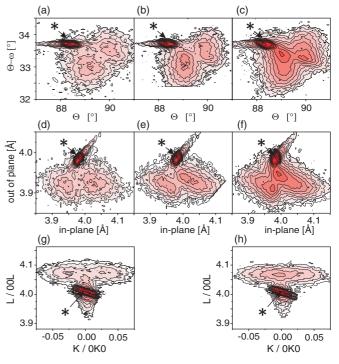

FIG. 7. (Color online) XRD-RSMs around $(203)_c$ of BiFeO₃ films grown on SmScO₃(110). Films with three different thicknesses were measured: (a) and (d) 13 nm, (b) and (e) 26 nm, (c) and (f) 38 nm, and the data are shown in two ways, $\Theta - \omega$ vs 2Θ (a)–(c) and transformed into lattice parameters (d)–(f). XRD-RSMs around (004) for (g) 13 nm and (h) 38 nm film on SmScO₃(110). The K and L axes are the Miller indices in pseudocubic notation for the SmScO₃ substrate and are parallel to the in-plane and out-of-plane direction of the sample surface. The substrate peaks are labeled with (*). All maps are displayed in logarithmic color code.

B. BiFeO₃ films grown with SrRuO₃ bottom electrode

The SrRuO₃ bottom electrode exerts important influence on the BiFeO₃ film growth and properties due to its different termination, electrical properties, structure, and film quality. For SrTiO₃ and DyScO₃ substrates, high quality SrRuO₃ films were achieved. XRD measurements reveal fully strained films (Fig. 10) and AFM measurements show that the terrace structure of the substrate is maintained (not shown). However, for GdScO₃ and SmScO₃ the lattice mismatch between SrRuO₃ and the substrate is so large that even 5 to 10 nm thick SrRuO₃ films relax partly. From XRD measurements, it can be inferred that the strain acting on BiFeO₃ is actually -0.1% and +0.5% for GdScO₃ and SmScO₃ substrates, respectively. This means that even though the pseudocubic lattice constant of GdScO₃ is slightly bigger than the one of BiFeO₃, the BiFeO₃ film on GdScO₃ substrate with SrRuO₃ bottom electrode is compressively strained. In case of the GdScO₃ substrate, the SrRuO₃ morphology exhibits terraces on which small islands were formed, whereas for SmScO₃ substrates the SrRuO₃ showed mainly an island growth mode. Due to the bad SrRuO₃ film quality on GdScO₃ and SmScO₃, the growth conditions of BiFeO₃ differ in comparison to SrTiO₃ and DyScO₃ substrates on which high quality SrRuO₃ bottom electrodes were grown. Moreover, it is likely that the electronic properties of the SrRuO₃ layers grown on

EPITAXIAL STRAIN AND ELECTRIC BOUNDARY ...

PHYSICAL REVIEW B 84, 094105 (2011)

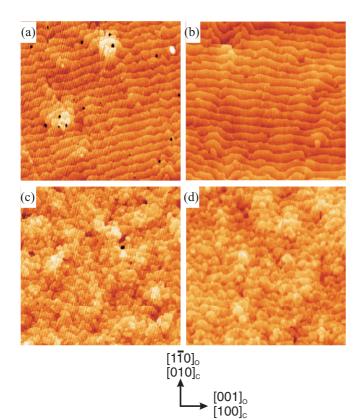

FIG. 8. (Color online) AFM images of the surface morphology of 30 nm thick BiFeO₃ films grown on (a) SrTiO₃(001), (b) DyScO₃(110), (c) GdScO₃(110), and (d) SmScO₃(110), with SrRuO₃ bottom electrode. All images are $4 \times 4 \mu m^2$.

 $GdScO_3$ and $SmScO_3$ are significantly different than for the $SrRuO_3$ deposited on $SrTiO_3$ and $DyScO_3$.²⁵ Figure 8 shows the morphology of the BiFeO₃ films on all four substrates. All films exhibit one unit cell high terraces, although more disordered for films on $GdScO_3$ and $SmScO_3$.

To investigate the domain configuration PFM measurements were performed on all films. The VPFM images reveal that all films have an uniform polarization pointing downward, probably due to the electrical properties of SrRuO₃,⁹ and are not shown here. In the case of SrTiO₃ and DyScO₃ substrates, the LPFM images depend again strongly on the cantilever orientation, as can be seen in Figs. 9(a) and 9(b). While scanning with the cantilever aligned perpendicular to the terraces the films show an evenly distributed domain distribution, with different domain sizes and shapes. On the other hand, by scanning with the cantilever aligned along the terraces, a preferred contrast occurs in the LPFM images. Combining VPFM and both LPFM images one can conclude that for SrTiO₃ and DyScO₃ substrates only the structural variants r_3 and r_4 occur, with only the two polarization directions P_3^- and P_4^- [Fig. 9(e)]. The domain patterns in the LPFM images for films on GdScO₃ and SmScO₃ substrates are very similar and show almost no preferred domain variants for both cantilever orientation [Figs. 9(c) and 9(d)]. Therefore all structural variants with the polarization directions P_1^- , P_2^- , P_3^- , and P_4^- occur. The appearance of all structural variants is in agreement with the island formation during the growth of the SrRuO₃ layer which annihilates the possible effects of the substrate asymmetry.

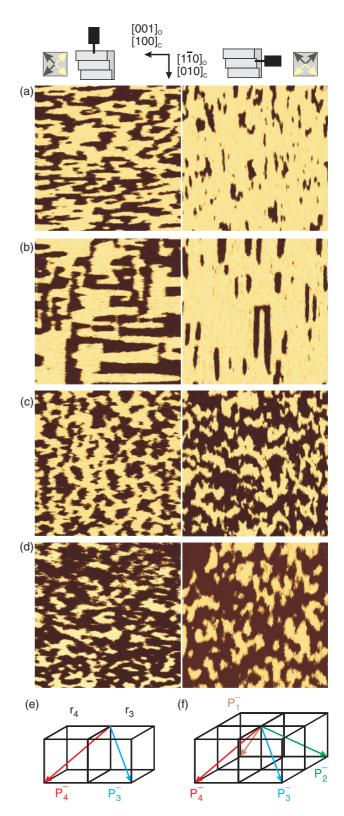

FIG. 9. (Color online) LPFM images of BFO films with SrRuO₃ bottom electrode on (a) SrTiO₃(100), (b) DyScO₃(110), (c) GdScO₃(110), and (d) SmScO₃(110). Samples were measured with the cantilever oriented along $[010]_c$ (left image) and $[100]_c$ (right image). The insets in the LPFM images show the two possible polarization directions for both contrasts. All images are $3 \times 3 \mu m^2$. Preferred directions of polarization are indicated for BFO films on (e) SrTiO₃ and DyScO₃ and for (f) GdScO₃ and SmScO₃.

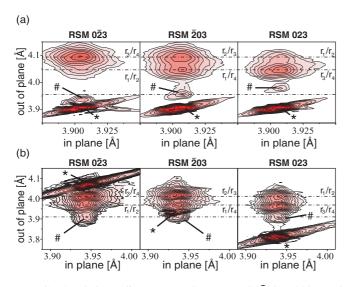

FIG. 10. (Color online) XRD-RSMs around $(\overline{2}03)$, (023), and (203) for a film on (a) SrTiO₃ and (b) DyScO₃ substrates with SrRuO₃ bottom electrode. Substrate peaks and SrRuO₃ peaks are labeled with (*) and (#), respectively.

In order to investigate the origin of the preferred directions observed for BiFeO₃ in case of SrTiO₃ and DyScO₃ substrates, RSMs around $(\overline{2}03)_c$, $(023)_c$ and $(203)_c$ were measured on those films. Figure 10(a) shows the result for the SrTiO₃ case. The peaks for SrRuO₃ have different out-of-plane parameters in the different RSMs, indicating that the SrRuO₃ layer is monodomain and that it kept its orthorhombic unit cell with a monoclinic distorted pseudocube.²⁶ The crystallographic orientation of SrRuO₃ is determined by the miscut direction. As sketched in Fig. 11(a) the occurring distortions in the BiFeO₃ films are opposed to the monoclinic ones of SrRuO₃. The origin of the domain suppression are the substrate terraces, which break the cubic substrate symmetry. The BiFeO₃ films grown directly on the SrTiO₃ substrate do not show this domain selection. Those films grow in a different mode as well, as they do not exhibit terraces anymore. Therefore, the electrical properties and surface chemistry of the SrRuO₃ layer appear to be necessary for the preferred domain variants of the BiFeO₃ on SrRuO₃/SrTiO₃(001).

The RSMs for the film on DyScO₃ are shown in Fig. 10(b). The SrRuO₃ grows on DyScO₃(110) a tetragonal structure, as reported by Vailionis *et al.*²⁷ The distortions of BiFeO₃ are aligned in the same direction as the distortion of the substrate [Fig. 11(b)], similar to the case without the SrRuO₃ bottom electrode. However, with respect to the terrace alignment these are the same structural variants as on SrTiO₃. To determine the origin of the domain selection in case of DyScO₃ substrates, whether it is the terrace alignment or the substrate distortion, films were grown on substrates with opposite miscut directions, as depicted in Figs. 11(b) and 11(c). PFM and XRD measurements reveal (not shown) that the preferred domain variants change to r_1 and r_2 when changing the offcut direction. This proves that the terrace alignment is the driving mechanism for domain suppression.

Macroscopic ferroelectric polarization measurements were performed to study the influence of epitaxial strain and domain variants on the magnitude of the switchable polarization.

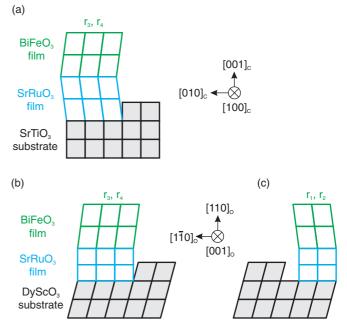

FIG. 11. (Color online) Schematics of preferred domain configuration for BiFeO₃ films with SrRuO₃ bottom electrode on SrTiO₃ (a) and DyScO₃ with two different miscut direction (b) and (c).

Amorphous SrRuO₃ top electrodes covered with platinum $(60 \times 60 \ \mu m^2$ in size) were deposited on the 30 nm thick BiFeO₃ films. The voltage was applied to the top electrode. Figures 12(a) and 12(b) show the ferroelectric polarization and switching currents of BiFeO₃ films on SrRuO₃-covered SrTiO₃, DyScO₃, and GdScO₃ substrates. In agreement with other reports,^{28,29} there is a slight decrease of switchable polarization for BiFeO₃ films under tensile strain. As mentioned already above, the film on GdScO₃ is not fully strained.

For the film on SmScO₃, smaller electrodes had to be chosen because of existing leakage paths for bigger ones. Hence, $12 \times 12 \,\mu\text{m}^2$ amorphous platinum electrodes were deposited on top of the sample. The drawback of the small electrodes lies in the big relative error of more than 25% for the electrode area determination. Therefore, the data from the film on SmScO₃ cannot be compared reliably with the other films. It can be seen however, that the ferroelectric polarization is of the same order of magnitude.

Although the different films studied here have different number of structural variants, the spontaneous polarization has the same order of magnitude. In contrast to what was reported for BiFeO₃ on low miscut $SrTiO_3(001)$ substrates with four structural variants we see no major difference in the magnitude of switchable polarization.⁷ There seem to be no pinned domain walls in our films with four structural variants.

All films have a strong imprint of about -550 kV/cm. To exclude the possibly bad interface with the amorphous SrRuO₃ top electrode as an origin of this imprint, a BiFeO₃ film with SrRuO₃ bottom electrode and *in situ* epitaxial top electrode was grown. The *in situ* epitaxial top electrodes had to be patterned in the top film afterwards by an etching procedure. Because SrRuO₃ is very inert to acids, La_{0.7}Sr_{0.3}MnO₃ (LSMO) was chosen as epitaxial top electrode, with the drawback of an electrically asymmetric LSMO/BiFeO₃/SrRuO₃

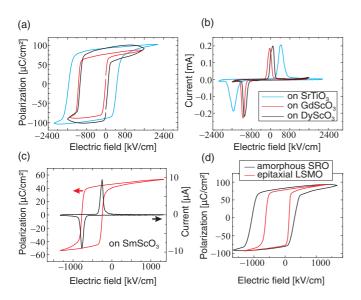

FIG. 12. (Color online) Ferroelectric polarization loop (a) and its corresponding current (b) for films on SrRuO₃-covered SrTiO₃, DyScO₃, and GdScO₃ measured at 100 K and 1 kHz with amorphous SrRuO₃ top electrodes ($60 \times 60 \ \mu m^2$). (c) Ferroelectric polarization and corresponding current for film on SmScO₃, measured at 100 K and 1 kHz with amorphous platinum top electrodes ($12 \times 12 \ \mu m^2$). (d) Ferroelectric polarization loop for films on DyScO₃ substrate with $60 \times 60 \ \mu m^2$ amorphous SrRuO₃ and epitaxial La_{0.7}Sr_{0.3}MnO₃ top electrodes, measured at 10 K and 1 kHz.

system. Platinum capacitors of $60 \times 60 \ \mu m^2$ in size were deposited on the epitaxial LSMO top electrode and the remaining LSMO layer was etched. As seen in Fig. 12(d) the film with epitaxial LSMO has slightly lower imprint, but it is still very pronounced. The coercive field is, however, distinctly reduced in case of epitaxial electrodes. Hence, the quality of the interface with the electrodes seems to be an important parameter for the coercive field.

The imprint might be connected to the polarization pointing preferentially toward the SrRuO₃ bottom electrode. In contrast, the films grown on the insulating substrate had a preferred direction upward, especially for BiFeO₃ grown on SrTiO₃ [Fig. 3(a)]. A uniform polarization pointing toward the SrRuO₃ bottom electrode of a La:BiFeO3 film has already been reported and could be correlated to the surface carrier density of SrRuO₃, which allows a full screening of the polarization at the interface.⁹ There are many reports for several material systems in literature, showing that there exists a preferred direction of polarization, which depends on the type of interface. For example, the direction of polarization for a 30 nm thick Pb(Zi_{0.2}Ti_{0.8})O₃ film on LSMO bottom electrode points downward with an imprint of -1.2 V, whereas for SrRuO₃ bottom electrode the polarization is pointing upward.³⁰ In PbTiO₃ films grown on SrRuO₃/SrTiO₃ a transition from a polarization pointing downward for films thinner than 20 nm to a polarization pointing upward for thicker films occurs.³¹ In addition, for BiFeO₃ on LSMO electrode it has been reported that there exists a strong pinning of the polarization at the interface, due to an induced polarization in the LSMO layer.³² Hence, among others, the role of the interface with the bottom electrode seems to be very important in imposing a preferential orientation of epitaxial ferroelectric films. Some analytical tools might help to understand this behavior, for example, soft x-ray scattering investigations of the Pb(Zr,Ti)O₃/LSMO system revealed that the Ti⁴⁺ ions at the interface have a different 3*d*-orbital character depending on the direction of polarization.³³ Therefore, a preferred direction of polarization might be a way to minimize the interfacial energy.

IV. CONCLUSIONS

The domain variants formed in epitaxial $BiFeO_3$ films grown on single crystal substrates depend strongly on several factors: the growth mode of the $BiFeO_3$ film, the type of interface, the substrate symmetry, and the substrate miscut direction.

BiFeO₃ films grown directly on cubic SrTiO₃ substrates exhibit all four structural domain variants, whereas for films grown on the orthorhombic rare earth scandates two structural domain variants are suppressed, which is a result of the monoclinic symmetry of these substrates when cut in (110) direction. In addition, stripe domain patterns were formed regardless of compressive and tensile stresses. For tensile strain, as it is the case of BiFeO₃ grown on GdScO₃(110) and SmScO₃(110), the stripes have widths smaller than 10 nm for 26 nm thick films, and a rotation of the BiFeO₃ unit cell occurs within the first 20–30 nm.

Coherently strained BiFeO₃ films grown on SrTiO₃ and DyScO₃ substrates with a step flow grown SrRuO₃ bottom electrode maintained the terrace morphology of the 0.15° miscut substrate, which, in contrast to the films without SrRuO₃, plays an important role in the structural domain selection. Films on GdScO₃ and SmScO₃ with SrRuO₃ electrode are partly relaxed and do not show any structural domain suppression. This might be due to the bad SrRuO₃ surface morphology, because step-flow growth could not be achieved anymore. All films show very similar values for the switchable polarization, independently of the number of structural variants within the film and of strain state.

ACKNOWLEDGMENTS

F. J. would like to thank Dr. Wei Peng for fruitful discussions and help with the XRD measurements. Financial support by DFG through SFB 762 is gratefully acknowledged.
