ABSTRACT

Allosteric modulators, by targeting the less-conserved allosteric sites, represent an innovative strategy in drug discovery. These modulators have a distinctive advantage over orthosteric ligands that attach to the conserved, functional orthosteric sites. However, in structure-based drug design, it remains unclear whether allosteric protein structures determined without orthosteric ligands binding are suitable for allosteric drug screening. In this study, we performed large-scale conformational samplings of six representative allosteric proteins uncomplexed (*apo*) and complexed (*holo*) with orthosteric ligands to explore the effect of orthosteric site binding on the conformational dynamics of allosteric sites. The results, coupled with the redocking evaluation of allosteric modulators to their *apo* and *holo* proteins using their MD trajectories, indicated that orthosteric site binding had an effect on the dynamics of the allosteric sites and allosteric modulators preferentially bound to their *holo* proteins. According to the analysis data, we constructed a new correlation model for quantifying the allosteric site change driven by substrate binding to the orthosteric site. These results highlight the strong demand to select *holo* allosteric proteins as initial inputs in structure-based allosteric drug screening when the distance between orthosteric and allosteric sites in the protein is below 5 Å, which is expected to contribute to allosteric drug discovery.

INTRODUCTION

Allostery, or allosteric regulation, regarded as 'the second secret of life', fine-tunes most biological processes and controls physiological activities^{1,2}. Dysregulation of protein allostery can lead to human diseases; therefore, recovery of malfunctional proteins to their normal functions by allosteric modulators provides a rich landscape for new therapeutics^{3,4}.

Allosteric modulators, by targeting the less conserved allosteric sites that are topologically and spatially distinct from the conserved, functional, orthosteric sites, bear distinctive advantages compared to orthosteric ligands, including higher specificity and lower toxicity⁵⁻⁷. Despite a number of potential advantages endowed by allosteric therapeutics, in recent years, the discovery allosteric drugs has been challenging. Indeed, a vast majority of allosteric modulators have been identified serendipitously by means of high-throughput screening⁸. This difficulty has severely hindered progress in the development of allosteric drugs over the past several decades, as demonstrated by the limited number of allosteric modulators reported to date^{9,10}.

Due to recent advances in X-ray and NMR spectroscopies, a considerable number of allosteric proteins complexed or uncomplexed with their allosteric modulators have been discovered¹¹⁻¹³. With the characterization of allosteric proteins and allosteric protein-modulator complexes, the unique hallmarks of allosteric proteins, allosteric modulators, and allosteric sites have been increasingly characterized^{8,14-16}. The increased availability of structural data, coupled with the advances in computer power, facilitates the development of structure-based computational methods for detection of

1
2
3
4 allosteric sites in proteins because identification of allosteric sites is the first step for *in*
5
6 *silico* screening of potential allosteric modulators. To date, a series of structure-based
7
8
9 predictive models have been developed to predict allosteric sites and deployed to web
10
11
12 servers, such as Allosite¹⁷, PARS¹⁸, and SPACER¹⁹.

13
14 A prerequisite for the success of *in silico* screening is to provide an input structure
15
16 that can represent a major physiological conformation in the cellular environment. As
17
18 in the case of protein allostery, binding of an allosteric modulator to its allosteric site
19
20 alters the shape and dynamic of the orthosteric site, suggesting that there is signal
21
22 propagation from allosteric to orthosteric sites²⁰⁻²². Consistently, biophysical
23
24 experiments indicated that orthosteric site occupancy by its endogenous substrate or
25
26 exogenous ligands can also alter the conformational dynamics of allosteric site,
27
28 reflecting the bidirectional regulation between allosteric and orthosteric sites^{23,24}. When
29
30 the known allosteric proteins deposited into the Allosteric Database (ASD)⁹ are under
31
32 intense scrutiny, a number of allosteric proteins are crystallized without the endogenous
33
34 substrates or exogenous ligands bound to their orthosteric sites (hereafter called *apo*
35
36 proteins). This observation raises a significant question: are the *apo* (orthosteric site-
37
38 unbound) protein structures suitable as initial conformations for *in silico* allosteric
39
40 screening?
41
42
43
44
45
46
47
48
49

50 To address this question, we sampled large-scale conformations of the *apo* and *holo*
51
52 (orthosteric site-bound) proteins to quantify the effect of orthosteric site binding on the
53
54 conformational dynamics of the allosteric site. Six representative allosteric proteins
55
56 were selected, including tryptophanyl-tRNA synthetase (TrpRS), human monoamine
57
58
59
60

1
2
3
4 oxidase B (MAO B), N-acetylglucosamine-1-phosphate uridyltransferase (GlmU),
5
6
7 macrophage migration inhibitory factor (MIF), ERK/MAP kinase (MAPK), and
8
9 GTPase K-Ras4B oncoprotein. The analysis results revealed that the conformational
10
11
12 dynamics of allosteric sites changed significantly in response to orthosteric site binding.
13
14 Furthermore, redocking of allosteric modulators to the *apo* and *holo* proteins extracted
15
16
17 from the MD trajectories indicated that allosteric modulators preferentially bound to
18
19
20 their holo proteins. Finally, we constructed a new correlation model for evaluating the
21
22
23 allosteric site change driven by substrate binding into the orthosteric site. Taken
24
25
26 together, these results support the use of the *holo* allosteric proteins as initial inputs in
27
28
29 structure-based drug screening, which is expected to contribute to allosteric drug

discovery.

METHODS

Dataset

First, we manually picked allosteric proteins from our constructed ASD⁹ in which the orthosteric site is adjacent to the allosteric site. Next, we examined the residues located in orthosteric and allosteric sites and ruled out the proteins without shared residues in the orthosteric and allosteric sites. The final selected proteins consisted of six enzymes: TrpRS (PDB ID 1MAU)²⁵, ERK/MAP kinase (MAPK) (PDB ID 4ANB)²⁶, K-Ras4B (PDB ID 4LUC)²⁷, GlmU (PDB ID 2V0I)²⁸, MAO B (PDB ID 2XCG)²⁹, and MIF (PDB ID 3IJJ)³⁰ (Figure 1). Moreover, the phylogenetic tree constructed for the six allosteric proteins displayed a wide distribution of these allosteric proteins, indicating that the allosteric proteins belong to different protein families.

Preparation of simulated systems

In all six allosteric proteins, the *holo* forms were obtained by removing the allosteric modulators from the allosteric sites. The *apo* forms were obtained by removing both allosteric modulators and orthosteric ligands from the allosteric and orthosteric sites. The chain A was selected for the dimer of MAO B and K-Ras4B. The solvent molecules except crystal water were deleted and the metal ions in pockets were kept. In the MAO B, there has a flavin cofactor that was reserved in both holo and apo forms during simulations. In each protein, a pair of face-to-face residues located in the middle of the tunnel between the allosteric and orthosteric sites were defined as bayonet residues. In addition, the orthosteric and allosteric site residues were annotated. Special case is the crystal structure of GlmU (PDB ID 2V0I)²⁸, because there is a lack of an allosteric ligand. However, the crystal structure of GlmU in complex with an allosteric inhibitor (PDB ID 2VD4)³¹ reveals that allosteric site is adjacent to orthosteric site. We thus aligned the two crystal structures to monitor the minimum distance between the two ligands and define the bayonet residues.

The proteins were modeled using the AMBER FF99SB force field³², while the orthosteric ligands were modeled using the generalized AMBER force field (GAFF)³³. Geometry optimization and the electrostatic potential calculations on the allosteric modulators or orthosteric ligands were performed at the HF/6-31G* level of Gaussian09³⁴, and the partial charges were calculated with the restrained electrostatic potential (RESP) fitting method³⁵. The force field parameters for the allosteric modulators or orthosteric ligands were created by the Antechamber package. For the metal atoms, GTP and ATP were obtained from the AMBER parameter database³⁶. Each system was dissolved in a truncated octahedral box of TIP3P water³⁷ and was neutralized with counter ions.

MD simulations

MD simulations for each system were performed using the AMBER11 package³⁸⁻⁴¹. First, to remove bad contacts in the initial structures, steepest descent and conjugate gradient algorithms were performed for energy minimization. After energy minimization, each system was gradually heated from 0 to 300 K in 100 ps. Subsequently, constant temperature equilibration at 300 K for 300 ps was performed to adjusting the solvent density. Finally, 200-ns MD simulations were carried out for each system in the NPT ensemble with periodic boundary conditions. An integration step of 2 fs was used, and the long-range electrostatic interactions were treated by the particle mesh Ewald (PME) method⁴². A cut-off of 10 Å was used for limiting the direct space interactions. The SHAKE method⁴³ was applied to constrain all covalent bonds involving hydrogen atoms. Each simulation was coupled to at a temperature of 300 K and a pressure of 1.0 atm by applying the Langevin algorithm⁴⁴.

Dynamical cross-correlation matrices

Dynamic cross-correlation matrices (DCCM) were used to detect time-correlation motion in protein, which is composed of the fluctuation cross-correlations coefficient in the positions of C α atoms during the MD simulation.⁴⁵ The normalized cross-correlation function C_{ij} was calculated according to Eq. (1):

$$C_{ij} = \frac{\langle \Delta \vec{r}_i(t) \cdot \Delta \vec{r}_j(t) \rangle}{(\langle \Delta \vec{r}_i(t)^2 \rangle \langle \Delta \vec{r}_j(t)^2 \rangle)^{1/2}} \quad (1)$$

$$\Delta \vec{r}_i(t) = \vec{r}_i(t) - \langle \vec{r}_i(t) \rangle \quad (2)$$

where $\vec{r}_i(t)$ and $\vec{r}_j(t)$ are the spatial positions of C α atoms corresponding residues i and j at time t . The value of C_{ij} is between -1~1. $C_{ij} > 0$ indicated the C α atoms between residues i and j exhibited motions in same direction along a given spatial coordinate, whereas $C_{ij} < 0$ indicated the C α atoms between residues i and j exhibited

1
2
3 motions in opposite directions along a given spatial coordinate. $C_{ij} = 0$ indicated the
4
5 $\text{C}\alpha$ atoms exhibited motions between residues i and j independently. The correlations
6
7 were calculated by the *ptraj* module in AMBER.
8
9

10 11 12 13 **RESULTS AND DISCUSSION**

14 15 16 **Correlation of allosteric site volume and bayonet residues**

17
18 To test our assumption that binding to the orthosteric site has an effect on the dynamics
19
20 of allosteric site, we first monitored potential dynamic changes between two bayonet
21
22 residues using 5000 frames from the last 100 ns trajectories. Next, the allosteric pocket
23
24 volumes of the *apo* and *holo* forms, which have a cavity shape, were calculated using
25
26 MDpocket⁴⁶. The results for all systems are displayed in the scatter diagram to
27
28 intuitively show distance and volume ($\ln V$) variations (Figure 2). In TrpRS (Figure
29
30 2A), ERK/MAP kinase (MAPK) (Figure 2B), K-Ras4B (Figure 2C), and GlmU (Figure
31
32 2D), both the allosteric site volume and bayonet residue distance increased significantly
33
34 in the *holo* forms compared to the *apo* forms. However, in MAO B (Figure 2E), no
35
36 appreciable differences in the allosteric site volume or bayonet residue distance
37
38 between the *holo* and *apo* forms were observed. This exception is partly due to the
39
40 evidence that the allosteric site is relatively far from the active site (Figure 1), thereby
41
42 leading to the subtle effect of orthosteric site binding on the dynamics of allosteric site
43
44 for our timescale. Unexpectedly, in MIF (Figure 2F), both the allosteric site volume
45
46 and bayonet residue distance decreased significantly in response to orthosteric site
47
48 binding. Overall, regardless of the enlargement or contraction of the allosteric sites, the
49
50
51
52
53
54
55
56
57

2
3
4 topological structures of the allosteric sites changed remarkably in reaction to
5
6 orthosteric site binding.
7

9 **Concerted atomic motions of orthosteric and allosteric sites**

10
11 Given the influence of orthosteric site binding on the conformational dynamics of
12 the allosteric site, we next analyzed DCCM using 5000 frames from the last 100 ns
13 trajectories to reveal concerted atomic motions of orthosteric and allosteric sites in the
14 *apo* and *holo* forms, respectively. In this analysis, we primarily focused on the regions
15 formed by orthosteric and allosteric sites (the residues within 5 Å of ligands), as well
16 as those between them, which are named a shared community. Furthermore, the
17 differences in DCCM between the *apo* and *holo* forms were calculated to understand
18 the altered motions of the allosteric site upon binding of the corresponding orthosteric
19 ligand.
20
21

23
24
25
26
27
28
29
30
31
32
33

34
35 In TrpRS (Figure 3A), ERK/MAP kinase (MAPK) (Figure 3B), K-Ras4B (Figure
36 3C), and GlnU (Figure 4A), the correlated motions of allosteric sites, orthosteric sites,
37 and shared community remarkably increased in the *holo* forms compared to the *apo*
38 forms, strongly supporting the notion that orthosteric ligand binding to the orthosteric
39 site affects the conformational dynamics of the corresponding allosteric site. In the four
40 allosteric proteins, the allosteric sites are proximal to their orthosteric sites. As a result,
41 the fluctuations in the orthosteric sites induced by orthosteric ligand binding can readily
42 propagate to their nearby allosteric sites through the shared community. In MAO B
43 (Figure 4B), the correlated motions of the allosteric site were unaffected in the presence
44 of an allosteric ligand at the allosteric site because of the distant location of the allosteric
45
46
47
48

53
54
55
56
57
58
59
60

1
2
3
4 and orthosteric sites. This result is consistent with the analysis of allosteric site volume
5
6 and bayonet residue distance in MAO B. In MIF (Figure 4C), the correlated motions of
7
8 the allosteric site in the *holo* form slightly increased in relation to the *apo* form. Taken
9
10 together, the results of the DCCM analysis demonstrate that binding to the orthosteric
11
12 site has the potential to alter the dynamics of the allosteric site.
13
14
15

16 **Evaluation of allosteric molecular binding mode**

17
18
19 The assessment of the allosteric site volume and the coupled motions of the
20
21 allosteric site suggest the variation of the allosteric site's topological structure as a
22
23 consequence of orthosteric site binding. To further verify the significance of
24
25 conformational variation in the allosteric sites of the *holo* forms, redocking of allosteric
26
27 modulators to their corresponding allosteric sites in both the *apo* and *holo* forms was
28
29 performed using Glide⁴⁷. First, the hierarchical clustering analysis was performed with
30
31 the last 100 ns MD trajectories (10000 frames) of the *apo* and *holo* forms, and each
32
33 system was grouped into five clusters. Representative structure was extracted from each
34
35 cluster of the *apo* and *holo* forms of each system, respectively. The five representative
36
37 structures obtained after cluster analysis can represent a wide range of different
38
39 conformational states. Next, redocking of allosteric modulators to the allosteric sites of
40
41 the five respective structures in both the *apo* and *holo* forms was performed, and 32
42
43 docked poses were obtained for each allosteric modulator to the allosteric sites of *apo*
44
45 and *holo* forms, respectively. Herein, we only considered the re-docked binding poses
46
47 of allosteric ligands. Therefore, the root-mean-squared-deviation (RMSD) of each
48
49 allosteric modulator between the native binding mode and the re-docked binding mode
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 was calculated, and the best result of each re-docked complex was used as an evaluation
5
6
7 criteria of the redocking binding mode.
8

9 In TrpRS (Figure 5A), ERK/MAP kinase (MAPK) (Figure 5B), K-Ras4B (Figure
10
11 5C), and GlmU (Figure 5D), the RMSD of the allosteric modulators docked into the
12
13 *holo* forms was significantly smaller than those docked into the *apo* forms. In MAO B
14
15 (Figure 5E), docked conformations of the allosteric modulator to the allosteric sites of
16
17 the *apo* and *holo* forms had no remarkable differences, reflecting no significant effect
18
19 of orthosteric site binding on the topology of the allosteric site for our timescale. In
20
21 MIF (Figure 5F), the RMSD of the allosteric modulator to the *holo* form was slightly
22
23 smaller than that to the *apo* form.
24
25
26
27
28
29

30 The redocking results suggest a difference in the geometrical conformation of
31
32 allosteric sites in the presence and absence of orthosteric site binding. Moreover, the
33
34 allosteric modulators can fit snugly into their allosteric sites in the presence of
35
36 orthosteric ligands, highlighting the significance of orthosteric site binding in re-
37
38 shaping the allosteric site. This principle can be applied for structure-based allosteric
39
40 molecule screening against the crystal structures of orthosteric ligand-bound proteins.
41
42
43
44

45 **Correlation of minimum distance between allosteric and orthosteric sites with** 46 47 **allosteric site volume** 48 49

50 The analyses of allosteric site volume, DCCM, and redocking experiments
51
52 revealed that when allosteric sites are in close proximity to orthosteric sites, the
53
54 conformational variations in allosteric sites are apparent upon the binding of the
55
56 orthosteric site. Thus, we hypothesize that the extent of allosteric site conformational
57
58
59
60

1
2
3
4 variations induced by the binding of the orthosteric site is dependent on the distance
5
6 between the allosteric and orthosteric sites. To validate this hypothesis, we correlated
7
8 the distance between allosteric and orthosteric sites with the perturbation of allosteric
9
10 site upon orthosteric site binding. The centroid distance between allosteric and
11
12 orthosteric sites was used as the location of the two sites, and the allosteric site volume
13
14 was used to evaluate the allosteric site conformational variation between the *apo* and
15
16 *holo* forms. The fitted curve of distances (d) and volume variations ($\Delta\bar{V}$) are shown in
17
18 Figure 6. The fitted curve can be formulated as
19
20
21
22
23

$$y = \exp(a + bx) \quad (3)$$

24
25 where y is the $\Delta\bar{V}$ of the allosteric site between the *holo* and *apo* forms, and x is the
26
27 d between the allosteric and orthosteric sites. The fitted constants a and b are 9.93 and
28
29 -1.17, respectively. Goodness of fit was evaluated with the R-square (R^2), where R^2
30
31 = 0.924.
32
33
34
35
36

37
38 Based on the curve, it is noticeable that if the distance between allosteric and
39
40 orthosteric site is less than 5 Å, the $\Delta\bar{V}$ of the allosteric site alters significantly with
41
42 the variation of distance. This finding indicates that when the allosteric site is close to
43
44 its orthosteric site, the conformational dynamics of the allosteric site will be markedly
45
46 changed after orthosteric site binding. However, if the distance between allosteric and
47
48 orthosteric sites is larger than 5 Å, the variation of distance has a minor effect on the
49
50 $\Delta\bar{V}$ of the allosteric site.

53
54
55
56
57

58 CONCLUSIONS

59
60

1
2
3
4 Due to the prominent functional importance of allostery in controlling
5
6 physiological activities and causing human diseases, allosteric drug development is an
7
8 innovative research strategy. Allosteric drugs do not compete with endogenous
9
10 substrates that occupy the conserved orthosteric sites. In contrast, they attach to the
11
12 structurally diverse allosteric sites, thereby possessing higher selectivity compared to
13
14 orthosteric drugs. However, the design of allosteric drugs is currently challenging
15
16 because unearthing the allosteric sites in proteins is a challenge^{4,48}. Indeed, the majority
17
18 of currently identified and characterized allosteric sites were adventitiously discovered
19
20 by biochemical experiments.⁴⁹⁻⁵⁰ In addition, in structure-based allosteric drug design,
21
22 the hit rate for allosteric screening is extremely low with notably few instances of
23
24 allosteric modulator identification via computational screening¹⁰. There is a lack of
25
26 knowledge regarding the interplay between allosteric and orthosteric sites.⁵¹
27
28
29
30
31
32
33
34

35 The recent unified view of allostery introduced by Nussinov and Tsai emphasizes
36
37 the existence of structural coupling between the allosteric and orthosteric sites^{3,52}. The
38
39 allosterically perturbed signals transmit from allosteric to orthosteric sites, thereby
40
41 affecting the functional activities of orthosteric sites. In a similar vein, using a Gaussian
42
43 network model to analyze motion correlation of allosteric proteins, Ma *et al.*⁵³ revealed
44
45 pronounced correlations between allosteric and orthosteric sites in both monomeric and
46
47 oligomeric allosteric proteins. These studies are indicative of the bidirectional
48
49 modulation between allosteric and orthosteric sites. In other words, allosteric site
50
51 binding enables reshaping of the corresponding orthosteric site and vice versa.
52
53
54
55
56
57

58 In the allosteric drug design, the appropriate selection of the allosteric site in the
59
60

1
2
3
4 three-dimensional structure becomes a high-priority goal, which determines the success
5
6 of allosteric modulator identification. In effect, a considerable proportion of allosteric
7
8 proteins are discovered without the presence of endogenous substrates or orthosteric
9
10 ligands bound to their orthosteric sites. To definitively elucidate the effect of orthosteric
11
12 site binding on the conformational dynamics of allosteric sites, we performed MD
13
14 simulations of six representative allosteric proteins in both *apo* and *holo* forms.
15
16 Through the analyses of allosteric site volume and correlated motions of allosteric and
17
18 orthosteric sites, we observed that when the allosteric and orthosteric sites are closely
19
20 positioned on the protein, the conformational plasticity of the allosteric site is markedly
21
22 affected by binding of the orthosteric ligand to the orthosteric site. As a result,
23
24 redocking experiments corroborated that the allosteric modulators prefer binding to
25
26 their corresponding allosteric proteins in the presence of a bound orthosteric site.
27
28 However, the correlation model indicates that the reverse regulation between allosteric
29
30 site and orthosteric site may depend on the distance between the two sites. Most likely,
31
32 when the distance between the orthosteric and allosteric sites in the protein is below 5
33
34 Å, it is advisable to select the crystal structures of allosteric proteins with their
35
36 orthosteric ligands bound as the initial inputs to structure-based allosteric drugs
37
38 screening.

FIGURES

Figure 1. Phylogenetic tree analyses of six representative allosteric proteins, including tryptophanyl-tRNA synthetase (TrpRS) (PDB ID 1MAU), human monoamine oxidase B (MAO B) (PDB ID 2XCG), N-acetylglucosamine-1-phosphate uridylyltransferase (GlmU) (PDB ID 2V0I), macrophage migration inhibitory factor (MIF) (PDB ID 3IJJ), ERK/MAP kinase (MAPK) (PDB ID 4ANB), and GTPase K-Ras4B (PDB ID 4LUC). Phylogenetic distance is proportional to branch length (the connecting lines). The allosteric and orthosteric sites in the proteins are extracted and depicted by splitpea and cyan, respectively. Allosteric modulators and orthosteric ligands in their corresponding allosteric and orthosteric sites are depicted by stick models.

Figure 2. Variations of the allosteric site volumes and bayonet residue distances in TrpRS (A), ERK/MAP kinase (MAPK) (B), K-Ras4B (C), and GlmU (D), MAO B (E), and MIF (F).

Figure 3. Dynamic cross-correlation maps (DCCM) reveal the extent of correlation for the orthosteric and allosteric sites as well as the shared community between them in the *apo* and *holo* forms of TrpRS (A), ERK/MAP kinase (MAPK) (B), and K-Ras4B (C). The absolute values for the differences in DCCM between the *apo* and *holo* forms are shown in the right panel. Motion occurring along the same direction is represented by positive correlation (orange), while anti-correlated motion occurring along the opposite direction is represented by negative correlation (green). 'S' and 'A' represent orthosteric and allosteric sites, respectively.

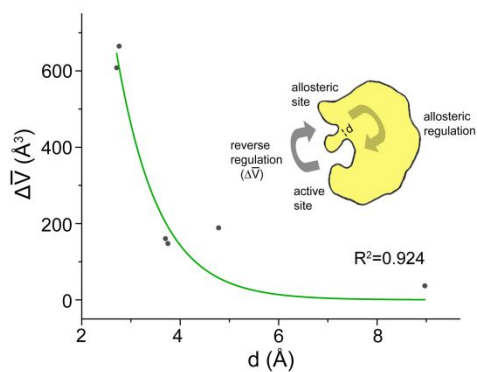

Figure 4. Dynamic cross-correlation maps (DCCM) reveal the extent of correlation for the orthosteric and allosteric sites as well as the shared community between them in the *apo* and *holo* forms of GlmU (A), MAO B (B), and MIF (C). The absolute values for the differences in DCCM between the *apo* and *holo* forms are shown in the right panel. Motion occurring along the same direction is represented by positive correlation
