1 Despite the importance of gelatinous zooplankton as components of marine ecosystems, both
2 ecologically and socio-economically, relatively little is known about population persistence
3 or connectivity in jellyfish. In the present study, we employed a combination of nuclear
4 microsatellite markers and sequence data from the mitochondrial cytochrome oxidase I (COI)
5 gene to determine levels and patterns of population genetic structuring in the holoplanktonic
6 jellyfish *Pelagia noctiluca* across the northeast Atlantic Ocean and Mediterranean Sea. Our
7 results indicate a high degree of connectivity in *P. noctiluca*, with little evidence of
8 geographical structuring of genetic variation. A small but significant differentiation of
9 Atlantic Ocean and Mediterranean stocks was detected based on the microsatellite data, but
10 no evidence of differentiation was observed with the mtDNA, probably due to the higher
11 power of the microsatellites to detect low levels of genetic structuring. Two clearly distinct
12 groups of genotypes were observed within the mtDNA COI, which probably diverged in the
13 early Pleistocene, but with no evidence of geographical structuring. Palaeodistribution
14 modelling of *P. noctiluca* at the Last Glacial Maximum (LGM; *ca.* 21 KYA) indicated large
15 areas of suitable habitat south of the species' current-day distribution, with little reduction in
16 area. The congruent evidence for minimal genetic differentiation from the nuclear
17 microsatellites and the mtDNA, coupled with the results of the palaeodistribution modelling,
18 supports the idea of long-term population stability and connectivity, thus providing key
19 insights into the population dynamics and demography of this important species.

Jellyfish (i.e. Phylum Cnidaria, Class Scyphozoa) exhibit a range of life history strategies. Most are metagenic, with an asexually reproducing, life-stage which is benthic (the polyp) and a free swimming or planktonic life stage (the medusa) among other, intermediate, stages (Arai, 1997). Such species are often constrained spatially by the need for accessible substratum for the settlement of polyps, skewing the distribution of resultant blooms towards near-shore waters (Boero *et al.*, 2008). In turn, metagenic jellyfish tend to exhibit population structure at modest scales (e.g. Lee *et al.*, 2013), predictable geographical distribution (e.g. Houghton *et al.*, 2006a) and relatively predictable, seasonal blooms (e.g. Houghton *et al.*, 2006b). Some jellyfish species, however, lack this benthic life stage enabling individuals to reproduce more readily in deeper off-shore waters (Boero *et al.*, 2008). *Pelagia noctiluca* is one such species with an apparently vast geographical range spanning the Atlantic, Pacific and Indian Oceans as well as their adjacent seas (Kramp, 1961; Mariottini, Giacco & Pane, 2008). Unlike blooms of metagenic jellyfish which arise from asexual strobilation at the seabed, the free-swimming medusae of *P. noctiluca* arise solely from sexual reproduction in the water column (Rottini Sandrini & Avian, 1983) which may convey a competitive advantage in deep-water habitats. At times, they can be brought onto continental shelves by oceanic water overflow, as is the case on the Irish Continental Shelf (Fraser, 1956; Bastian *et al.*, 2011). Indeed, in this region the species has been known to form aggregations $> 4^\circ$ of latitude (Doyle *et al.*, 2008) and to strand along hundreds of kilometres of coastline numerous times in recent years (Fleming, Harrod & Houghton, 2013).

Understanding the population connectivity of jellyfish has relevance far beyond the prediction of socio-economic impacts (Doyle *et al.*, 2014) with Pauly *et al.* (2008) describing them as ‘arguably the most important predators or the sea’. As one of the most venomous

48 species in UK/Irish waters (Mariottini *et al.*, 2008), *P. noctiluca* is certainly a noteworthy
49 predator yet, like many gelatinous species, is given scant consideration in fisheries or
50 ecosystem models (Pauly *et al.*, 2008; Sabates *et al.*, 2010; Doyle *et al.*, 2014; Purcell *et al.*,
51 2014). On a regional scale, the species first gained notoriety in the Northeast Atlantic
52 following a major fish kill at salmon farms in Northern Ireland in November 2007 causing
53 >£1M in damages in a single day (Doyle *et al.*, 2008). At first this mass incursion of this
54 species in Irish/UK coastal waters in 2007 was reported as unprecedented, yet subsequent
55 desktop studies revealed that *P. noctiluca* was reported in Irish/UK waters in 21 out of a
56 possible 95 years (i.e. 1890-1985; Doyle *et al.*, 2014). More recent studies using beach
57 strandings (Fleming *et al.*, 2013), fisheries by-catch data (Bastian *et al.*, 2011) and continuous
58 plankton recorder records (Licandro *et al.*, 2010) have confirmed that the species is a
59 longstanding feature of Irish/UK shelf waters. Given the ecological implications of these
60 reoccurring blooms (Doyle *et al.*, 2014) and the economic threat they pose to the Irish/UK
61 aquaculture industry (Doyle *et al.*, 2008; Fleming, Harrod & Houghton, 2013) there is a
62 pressing need to understand the demographic processes that underpin them better.

63 Within this context, molecular genetics provides the opportunity to explore patterns of
64 connectivity and recruitment underpinning blooms of *P. noctiluca*. Such concepts are
65 pertinent following Licandro *et al.* (2010), who suggested that the prevalence of *P. noctiluca*
66 in the northeast Atlantic (NEA) during 2007 and 2008 may reflect recent hydrographic
67 changes in the region. More specifically, the authors suggested that outbreaks of *P. noctiluca*
68 may follow the progression of the North Atlantic Current (NAC) and the continental slope
69 current (CSC), a northward branch of the Azores Current that flows along the eastern slope
70 boundary of the European basin (Garcia-Soto *et al.*, 2002; Pingree, 2002). It was Fraser
71 (1955) who first proposed that a subsurface current carries the “Lusitanian fauna” from the

72 outflow of the Gulf of Gibraltar to the NEA. The Lusitanian fauna contains zooplankton
73 species more typically of the Mediterranean, such as *P. noctiluca*.

74 From a molecular perspective most studies of population structure in *P. noctiluca* to date,
75 and indeed jellyfish in general (reviewed in Glynn, Houghton & Provan, 2015), have relied
76 heavily on the mitochondrial cytochrome oxidase I (COI) gene, occasionally with the
77 addition of ribosomal markers such as the internal transcribed spacers ITS1 and ITS2 (e.g.
78 Stopar *et al.*, 2010). While variable, the uniparental mode of inheritance and small effective
79 population size of the mitochondrial genome (relative to that of the nuclear genome) means
80 that the COI may not be an ideal candidate marker for such studies, particularly where levels
81 of genetic structuring are low. Indeed, previous studies have provided somewhat conflicting
82 findings with respect to connectivity in *P. noctiluca*. Using a combination of COI and ITS,
83 Stopar *et al.* (2010) observed a lack of genetic or geographic structuring across the Eastern
84 Atlantic and Mediterranean Sea whilst Miller, von der Heyden & Gibbons (2012) proposed
85 significant structuring between North and South Atlantic populations.

86 The application of high-resolution microsatellite markers has been effective in uncovering
87 cryptic population structure across the ranges of several marine species that had been thought
88 previously to be panmictic, such as eels (Wirth & Bernatchez, 2001) and microalgae (Provan,
89 2010). The sole population genetics of *P. noctiluca* to date that employed multiple, unlinked,
90 microsatellite markers focused on smaller-scale population structuring within the Eastern
91 Mediterranean and the Adriatic Seas (Agieri *et al.*, 2014). Consequently, in the present study
92 we employed the same microsatellites to analyse large-scale patterns of variation over a
93 similar area studied by Stopar *et al.* (2010), but with more extensive sampling of the
94 Northeast Atlantic, since population structuring as a result of historical processes have been
95 documented in the region for several marine species (reviewed in Provan, 2013). We wanted
96 to determine whether there was any significant differentiation between *P. noctiluca* from the

97 North Atlantic and populations from the Mediterranean Sea following the suggestions of
98 Licandro *et al.* (2010), the historical observation of Fraser (1955), and given that the Strait of
99 Gibraltar has been proposed to be a biogeographic barrier (reviewed in Patarnello, Volckaert
100 & Castilho, 2007), and also whether there was any finer-scale structuring within regions.

MATERIALS AND METHODS

SAMPLING AND DNA EXTRACTION

Samples were obtained from live-caught or fresh shore-stranded aggregations of *P. noctiluca* (locations are listed in Table 1). Specimens were washed in sea water before whole individuals in some cases, or umbrellar/gonadal flesh samples in most cases, were preserved in ethanol. All samples were stored in a 1:3 flesh to ethanol ratio, then stored at -20°C until extraction. Immediately prior to extraction, flesh was removed from the ethanol and dried using sterile paper towels, rinsed in double-distilled water and dried again on sterile paper towels to remove traces of ethanol. Genomic DNA was extracted using a modified version of the Porebski, Bailey & Baum (1997) CTAB phenol/chloroform protocol whereby extracted DNA which had been subjected to phenol and chloroform wash was stored in a 1:1 supernatant:isopropanol state at -20°C until needed for PCR, then pelleting and the alcohol wash were carried out before elution. Long term storage of eluted DNA resulted in loss of high molecular weight (genomic) DNA and reduced amplification success.

MICROSATELLITE GENOTYPING

We utilised eight of the nine microsatellite loci reported for *P. noctiluca* by Aglieri *et al.* (2014), with the exception of locus Pelnoc_40199, which could not be consistently amplified. Forward primers included a 19 bp M13 tail (CACGACGTTGTAAAACGAC) and reverse primers included a 7 bp tail (GTGTCTT). PCR was carried out in a total volume of 10 µl containing 100 ng genomic DNA, 10 pmol of 6-FAM-, PET- or HEX-labelled M13 primer, 1 pmol of tailed forward primer, 10 pmol reverse primer, 1x PCR reaction buffer, 200 µM each dNTP, 2.5 mM MgCl₂ and 0.25 U GoTaq Flexi DNA polymerase (Promega). PCR was carried out on a MWG Primus thermal cycler using the following parameters: initial

126 denaturation at 94 °C for 5 min followed by 45 cycles of denaturation at 94 °C for 30 s,
127 annealing at 57 °C for 30 s, extension at 72 °C for 30 s and a final extension at 72 °C for 5
128 min. Genotyping was carried out on an AB3730xl capillary genotyping system (Life
129 Technologies; Carlsbad, California, USA). Allele sizes were scored using LIZ size standards
130 and were checked by comparison with previously sized control samples.

131

132

MTDNA SEQUENCING

133 A 532 bp region of the *P. noctiluca* mtDNA COI gene was amplified using the primers Pn-
134 COI-F 5'-CCAGGGTCAATGCTTGGAG-3' and Pn-COI-R 5'-
135 CGAAGAAAGAGGTGTTAAAGTT-3' designed from GenBank sequence GQ376003.
136 PCR was carried out on a MWG Primus thermal cycler using the following parameters: initial
137 denaturation at 94 °C for 3 min followed by 45 cycles of denaturation at 94 °C for 30 s,
138 annealing at 58 °C for 30 s, extension at 72 °C for 1 min and a final extension at 72 °C for 5
139 min. PCR was carried out in a total volume of 20 µl containing 200 ng genomic DNA, 10
140 pmol of each primer, 1x PCR reaction buffer, 200 µM each dNTP, 2.5 mM MgCl₂ and 0.5 U
141 GoTaq Flexi DNA polymerase (Promega). 5 µl PCR product were resolved on 1.5% agarose
142 gels and visualised by ethidium bromide staining, and the remaining 15 µl were EXO-SAP
143 purified and sequenced in both directions using the BigDye sequencing kit (V3.1; Applied
144 Biosystems) and run on an AB 3730XL DNA analyser (Life Technologies; Carlsbad,
145 California, USA).

146

147

DATA ANALYSIS

148 Tests for linkage disequilibrium between pairs of microsatellite loci in each population were
149 carried out in the program FSTAT (V2.9.3.2; Goudet, 2002). Levels of polymorphism
150 measured as observed (H_O) and expected (H_E) heterozygosity averaged over loci for nuclear

151 microsatellites, and as haplotype (H) and nucleotide (π) diversity for mtDNA, were calculated
152 using the ARLEQUIN software package (V3.5.1.2; Excoffier & Lischer, 2010). Inbreeding
153 coefficients (F_{IS}) were estimated using FSTAT. To determine the mean levels of relatedness
154 between sampled individuals within populations, the relatedness coefficient (r) of Queller &
155 Goodnight (1989) was calculated using the GENALEX software package (V6.1; Peakall &
156 Smouse, 2006), and significance calculated using 999 permutations.

157 Levels of overall interpopulation differentiation as well as differentiation between Atlantic
158 and Mediterranean populations and population-pairwise differentiation were estimated from
159 allele (microsatellite) and haplotype (mtDNA) frequencies using Φ -statistics, which give an
160 analogue of F -statistics (Weir & Cockerham, 1985) calculated within the analysis of
161 molecular variance (AMOVA) framework (Excoffier, Smouse & Quattro, 1992), also using
162 the ARLEQUIN software package. A median-joining network showing the relationships
163 between the mtDNA haplotypes was constructed using the NETWORK software package
164 (V4.5.1.6; www.fluxus-engineering.com). The divergence time (T) between the two
165 observed groups of mtDNA haplotypes was estimated by calculating Nei's genetic distance
166 (D_A) using the DNAsp software package (Librado & Rozas, 2009), and by using the formula
167 $T = D_A / 2\mu$ (Nei & Kumar, 2000), where μ , the mutation rate per site per year, was 6.54×10^{-9} ,
168 the rate estimated previously for the Cnidarian *Obelia geniculata* (Govindarajan, Halanych
169 & Cunningham, 2005). In addition, tests for population expansion based on Tajima's D and
170 Fu and Li's F and a mismatch distribution analysis, which identifies characteristic "waves" in
171 the shape of the distribution resulting from expansion (Rogers and Harpending, 1992), were
172 carried out for both the large and the small clades in DNAsp.

173 To identify possible spatial patterns of gene flow, the software package BAPS (V5;
174 Corander, Waldmann & Sillanpää, 2003) was used to identify clusters of genetically similar
175 populations using a Bayesian approach. Ten replicates were run for all possible values of the

176 maximum number of clusters (K) up to $K = 14$, the number of populations sampled in the
177 study, with a burn-in period of 10 000 iterations followed by 50 000 iterations. Multiple
178 independent runs always gave the same outcome. To further identify possible spatial patterns
179 of gene flow, a principal coordinate analysis (PCA) was carried out in GENALEX. Inter-
180 individual genetic distances were calculated as described in Smouse & Peakall (1999), and
181 the PCA was carried out using the standard covariance approach.

182 Because of the genetic homogeneity revealed by the microsatellite loci studied, and to
183 compare the relative power of microsatellites and the mtDNA to detect low levels of
184 population differentiation, simulations were carried out using the POWSIM software package
185 (V4.0; Ryman & Palm, 2006). Simulations were carried out for an effective population size
186 of $N_e = 1\ 000$ to yield F_{ST} values of 0.001 – 0.020. In all cases, 1 000 replicates were run and
187 the power of the analysis was indicated by the proportion of tests that were significant at $P <$
188 0.05 using the observed allele frequencies for both the four microsatellite loci and the single
189 mtDNA COI region studied (for $F_{ST} = 0$ this corresponds to the Type I [α] error). For the
190 mtDNA, sample sizes were adjusted as recommended by Larsson *et al.*, (2009).

191

192

PALAEODISTRIBUTION MODELLING

193 Palaeodistribution modelling was carried out to determine the potential suitable range for *P.*
194 *noctiluca* at the Last Glacial Maximum (LGM; *ca.* 21 KYA) using the maximum entropy
195 approach implemented in the MAXENT software package (V3.3.3; Phillips, Anderson &
196 Schapire, 2006). Species occurrence data between 1950 and 2000 were downloaded from the
197 Global Biodiversity Information Facility data portal (www.gbif.org) and from the Ocean
198 Biogeographic Information System (www.iobis.org), and supplemented with our own
199 population data (188 occurrences in total). Current-day bioclimatic data (MARSPEC;
200 Sbrocco & Barber, 2013) were obtained at 5 minute resolution and models were generated

201 using cross-validation of ten replicate runs under the default MAXENT parameters. Model
202 performance was assessed based on the area under the receiver operating characteristic curve
203 (AUC). Models were projected onto reconstructed bioclimatic data for the LGM (ensemble
204 of five models: CNRM, ECBILTCLIO, FGOALS, HadCM and MIROC-322; Sbrocco,
205 2014).

RESULTS

GENETIC ANALYSES

No evidence of linkage disequilibrium was detected between any of the eight nuclear microsatellite loci analysed. Between six (Pelnoc_40622 and Pelnoc_44003) and 36 (Pelnoc_46263) alleles were detected, with a total of 136 (mean = 17 per locus). Within-population levels of observed (H_O) and expected (H_E) heterozygosity ranged from 0.426 (Rathlin Island) to 0.622 (Portofino; mean = 0.512) and from 0.554 (Rathlin Island) to 0.704 (Roscoff; mean = 0.636) respectively (Table 1). Levels of F_{IS} were significantly different from zero in twelve of the 14 populations, and ranged from 0.040 (Sole Bank) to 0.364 (Roscoff; mean = 0.193). Only two populations (Rathlin Island and Portofino) exhibited significant levels of relatedness between individuals ($r = 0.131$ and 0.136 respectively). Summary statistics by locus are given in Supplementary Table S1.

Mitochondrial COI sequences were obtained from 242 individuals. Two individuals were found to be heteroplasmic i.e. they displayed double peaks at multiple sites within the sequence, and were discarded from subsequent analyses. A total of 116 mitochondrial COI haplotypes were identified (Figure 2). These were structured into two groups (103 and 13 haplotypes respectively) separated by nine mutations. Only the most common haplotype was found in all 14 populations analysed, and 94 were found in a single individual. Within populations, between three (Galicia) and 19 (Villefranche-Sur-Mer) haplotypes were detected (mean = 12.21). Levels of haplotype (H) and nucleotide (π) diversity ranged from 0.700 (Galicia) to 0.979 (Sole Bank; mean = 0.904), and from 0.006 (North Atlantic and Dingle) to 0.015 (Malinbeg) respectively (Table 1). The divergence time between the two mtDNA groups was calculated as 1.529 MYA. The mismatch distribution analyses for the large (103 haplotypes) and small (13 haplotypes) clades indicated past population expansion (Figure

Page | 12

231 S1), as did the values for Tajima's D (large clade $D = -2.366$, $P < 0.01$; small clade $D = -$
232 1.783 , $P < 0.05$) and Fu and Li's F for the large clade ($F = -5.062$, $P < 0.05$), but not for the
233 small clade ($F = -1.964$, NS).

234 The analysis of molecular variance (AMOVA) revealed a small but significant overall
235 differentiation based on nuclear microsatellites ($\Phi_{ST[NUC]} = 0.025$; $P < 0.001$), but no
236 significant structuring based on the mtDNA COI ($\Phi_{ST[MT]} = -0.01$; NS; Table 2). Likewise,
237 the nuclear microsatellites indicated minimal but significant structuring between Atlantic and
238 Mediterranean populations ($\Phi_{CT[NUC]} = 0.020$; $P < 0.001$), but no significant structuring based
239 on the mtDNA COI ($\Phi_{CT[MT]} = -0.02$; NS; Table 2). Population-pairwise $\Phi_{ST[NUC]}$ values
240 ranged from -0.021 (Shetland Islands / Armorica Shelf) to 0.081 (Armorica Shelf /
241 Portofino), whilst pairwise $\Phi_{ST[MT]}$ values ranged from -0.074 (Bay of Biscay / Galicia) to
242 0.038 (Shetland Islands / Galicia). The BAPS analysis indicated that all the individuals
243 analysed were grouped into a single genetic cluster (100% probability). This was reflected in
244 the PCA, which showed no evidence of geographical structuring of individual multilocus
245 genotypes (Figure 3).

246 The simulation studies suggested that the nuclear microsatellite data were able to detect
247 F_{ST} values of as low as 0.005 at least 95% of the time (Figure 4). The mtDNA COI locus had
248 much lower power, only 38% for $F_{ST} = 0.005$, and could only detect $F_{ST} > 0.018$ with a
249 power of above 95%.

250

251 PALAEO-DISTRIBUTION MODELLING

252 For all models, AUC values were high (mean AUC = 0.908 ; SD = 0.040). The current-day
253 model indicated the presence of suitable habitat for *P. noctiluca* along western Europe
254 between 40°N and 70°N , including both the continental shelf and deeper waters off the Bay
255 of Biscay / northwest Iberia and the Norwegian Sea (Figure 5a). The palaeodistribution

256 model indicated a southward shift in suitable habitat, with the maximum northern limit off
257 the palaeocoastline around 50 °N, as well as more extensive habitat in the Mediterranean Sea
258 (Figure 5b).

The findings of the present study based on high-resolution nuclear and mitochondrial markers indicate a high degree of connectivity in *Pelagia noctiluca* across the Northeast Atlantic and the Mediterranean. There was little overall evidence of geographical structuring of genetic variation, and only a small but significant differentiation of Atlantic Ocean and Mediterranean stocks based on the microsatellite data. No evidence of differentiation was observed with the mtDNA, reflecting the higher power of the microsatellites to detect low levels of genetic structuring as indicated by the POWSIM analysis (Larsson *et al.*, 2009). The observed high levels of genetic diversity across the entire range of the study, as well as the Atlantic-wide distribution of the species (Miller, von der Heyden & Gibbons, 2012) and, indeed, the pan-global distribution of what is at least a species complex (Kramp, 1961; Mariottini, Giacco & Pane, 2008), would appear to be inconsistent with the concept of a Gulf of Gibraltar source of recurring aggregations in the Northeast Atlantic Ocean and Western Mediterranean Sea as proposed previously by Licandro *et al.*, (2010).

Despite the lack of any geographical structuring of genetic variation, two clearly distinct groups of genotypes were observed within the mtDNA COI, a feature also observed by Stopar *et al.* (2010). Such divergences tend to result from periods of isolation, usually associated with the climatic fluctuations that have occurred throughout the Pleistocene (Provan & Bennett, 2008; Provan, 2013). The timing of the divergence, however, places it in the early Pleistocene (*ca.* 1.5 MYA), thus ruling out recent episodes of glaciation as the causal factor in promoting divergence. Furthermore, the palaeodistribution model suggests the persistence of a large, continuous population of *P. noctiluca* during the LGM, similar to the scenario observed in the zooplankton *Calanus finmarchicus* (Provan *et al.*, 2009), but in contrast to our earlier findings in the metagenic jellyfish *Rhizostoma octopus* (Glynn,

284 Houghton & Provan, 2015). The fact that individuals from both the Atlantic and the
285 Mediterranean are represented by haplotypes from each clade, coupled with the observed lack
286 of any structuring in the microsatellite data set, further suggests extensive admixture since the
287 divergence of the two clades. If this mitochondrial structure were representative of
288 contemporary, ongoing, sympatric divergence, a commensurate divergence in microsatellite
289 lineages would be seen. As this is not the case, mitochondrial clades are likely vestigial
290 remnants of allopatric divergence, subjected to subsequent secondary contact, range overlap
291 and admixture. It is not obvious what factors would have promoted such a divergence *ca.* 1.5
292 MYA, but this period saw the start of a decrease in the North Atlantic Deep Water (NADW)
293 formation, among a range of other oceanic and climatic changes at the same time, prior to the
294 onset of the full glacial periods *ca.* 0.9 MYA (Raymo *et al.*, 1990; McClymont & Rosell-
295 Melé, 2005). Phylogenetic divergence dating to around the same time period (*ca.* 1.2 – 1.8
296 MYA) has been reported for the fish species *Dentex dentex* and *Lithognathus mormyrus*
297 (Bargelloni *et al.*, 2003), but in these cases this has resulted in separate Atlantic and
298 Mediterranean clades.

299 Significant F_{IS} values were observed in all but two of the populations sampled, which
300 could at first sight be attributed to intra-aggregation inbreeding, since it has been suggested
301 previously that reproduction generally occurs within persistent aggregations of *P. noctiluca*
302 (Russell, 1967; Zavodnik, 1987; Malej, 1989). This scenario, however, is not supported by
303 the analyses of within-population relatedness. Furthermore, the high levels of genetic
304 diversity observed across populations are inconsistent with long-term inbreeding. The
305 Portofino population was one of the two that exhibited significant within-population
306 relatedness between individuals, as well as being the most genetically distinct based on the
307 nuclear pairwise Φ_{ST} estimates. This might be seen as evidence for intra-aggregation
308 recruitment, but the same population did not exhibit a significant F_{IS} value. These apparent

309 discrepancies might be symptomatic of complex patterns of recruitment, including the
310 occurrence of Wahlund effects as a result of sampling distinct cohorts within a specific
311 geographical area that may have arisen through sweepstakes recruitment processes (Christie
312 *et al.*, 2010), but set against a long-term backdrop of high levels of broad-scale gene flow
313 over relatively long timescales. Nevertheless, the use of multiple, unlinked markers, and
314 particularly of markers which exhibit dissimilar mutation rates and patterns of inheritance in
315 the present study has proven useful in differentiating contemporary and historical signals of
316 population structure. Our findings point to the long-term persistence of a single, contiguous
317 European population of *P. noctiluca*, with minimal geographical structure. These results thus
318 provide key insights into the population dynamics and demography of this ecologically and
319 socio-economically important species.

We are grateful to Dave Stokes, the Marine Institute of Ireland, the Northern Ireland Environment Agency, Niall T. Keogh, Damien Haberlin, Lenaïg and Arzhela Hemery and others who provided samples, to Gemma Beatty for assistance in the laboratory, to Nils Ryman for advice on the POWSIM analyses, and to two anonymous Referees whose comments improved the manuscript. Fergal Glynn’s PhD was funded by the Department of Agriculture and Rural Development, Northern Ireland (DARDNI). Martin Lilley was funded by l’Agence Nationale de la Recherche projects “Ecogely” ANR-10-PDOC-005-01 and “NanoDeconGels” ANR-12-EMMA-0008. He would also like to thank the Centre for Environment, Fisheries & Aquaculture Science for facilitating the collection of the Shetland samples.

Figure Legends

Figure 1. Locations of sites sampled in this study.

Figure 2. Median-joining network showing relationships between the 116 haplotypes detected by sequencing the mtDNA COI region. Circle sizes are approximately proportional to haplotype frequency: smallest circle represents a single individual, largest circle represents 66 individuals. Each connection represents a single mutation and small open diamonds represent missing intermediate haplotypes.

Figure 3. Results of the PCA. The first three axes accounted for 21.71%, 18.12% and 17.29% respectively of the total variation (57.13%).

Figure 4. Results of the POWSIM analysis. The Y-axis represents the power of the markers to successfully recover the value of F_{ST} indicated on the X-axis, expressed as the proportion of 1000 simulations (see text for details). For $F_{ST} = 0$, this is the Type I (α) value.

Figure 5. Results of the species distribution modelling: (a) current-day model; (b) palaeodistribution model for the Last Glacial Maximum (LGM *ca.* 21 KYA). Darker blue areas indicate those more suitable for *P. noctiluca*. Yellow circles in (a) indicate occurrence data used to generate the models.

Figure S1. Results of the mismatch distribution analyses.
