17	Abstract
18	One of the main challenges faced by the nuclear industry is the long-term confinement of nuclear

waste. Because it is inexpensive and easy to manufacture, cement is the material of choice to store 19 large volumes of radioactive materials, in particular the low-level medium-lived fission products. 20 It is therefore of utmost importance to assess the chemical and structural stability of cement 21 containing radioactive species. Here, we use *ab-initio* calculations based on density functional 22 theory (DFT) to study the effects of ⁹⁰Sr insertion and decay in C-S-H (calcium-silicate-hydrate) 23 in order to test the ability of cement to trap and hold this radioactive fission product and to 24 investigate the consequences of its β -decay on the cement paste structure. We show that ⁹⁰Sr is 25 stable when it substitutes the Ca²⁺ ions in C-S-H, and so is its daughter nucleus 90 Y after β -decay. 26 Interestingly, ⁹⁰Zr, daughter of ⁹⁰Y and final product in the decay sequence, is found to be unstable 27 compared to the bulk phase of the element at zero K but stable when compared to the solvated 28 ion in water. Therefore cement appears as a suitable waste form for ⁹⁰Sr storage. 29

30 INTRODUCTION

Long-term confinement of radioelements produced by nuclear fission is one of the main 31 challenges faced by the nuclear industry. The primary focus of the nuclear waste storage 32 research has long been oriented towards host materials that can handle the large structural 33 damage induced by the high-energy α -decay of actinides.^{1,2} However, the need for optimizing 34 the vitrification process of actinides¹ and for increasing the capacity of repositories³ has 35 prompted the investigation of other forms of containers specifically targeted at low- and 36 medium-level waste. Such containers became urgently needed after the Fukushima disaster, 37 where large volumes of contaminated soils, water and buildings had to be quickly handled.^{4–7} 38 The main concern lies in the management of the medium-lived β^- -emitter fission products, 39 ¹³⁷Cs and ⁹⁰Sr.^{4,5} These represent the largest **fraction of the nuclear waste by activity**,⁸ 40 and have been found in the surrounding areas and in the cooling water of the damaged power 41 plants.^{4,5} They present important health risks: ¹³⁷Cs β^- decay is followed by a hazardous 42 γ emission, while ⁹⁰Sr can contaminate the animal and human population due to its ability 43 to replace the isovalent Ca ions that constitute bones and teeth (hence the name bone 44 seeker). This is particularly dangerous as β -emission in the bone produces a low-energy 45 electron cascade that can reach stem cells in the bone marrow, this being a major cause of 46 leukaemia. 47

 β^{-} decay produces modifications of the host matrix chemistry and can also influence its 48 mechanical properties. The three main processes following β -decay are: (1) the emission of 49 the β electron at MeV energies, (2) the recoil of the transmuted nucleus with kinetic energies 50 in the eV range due to conservation of momentum, and (3) the electronic rearrangement 51 around the transmuted nucleus due to the sudden increase in nuclear charge $(Z \rightarrow Z + 1)$. 52 All of these processes interact with the host in different ways.^{1,9–11} Recent theoretical studies 53 of the effects of transmutation due to β^- decay of ¹³⁷Cs and ⁹⁰Sr in ceramics and oxides¹² 54 showed important chemical and structural modifications of the host material in the case 55 of radioparagenesis^{11,13} in which a solid-state daughter phase is derived radiogenically by 56 a parent phase. These studies enable the design of waste forms with improved mechanical 57 properties by means of transmutation, thus opening a promising avenue for long-term nuclear 58 waste containment. A different, although related matter is the assessment of the aging of 59 materials partially contaminated by hosting nuclear waste, which is the main focus of the 60

61 present work.

Here we investigate the local effects of ⁹⁰Sr contamination and transmutation on cement. 62 ⁹⁰Sr (half-life 28.79 years) undergoes two successive β^- decays to ⁹⁰Y (half-life 64 hours), and 63 to ⁹⁰Zr (stable). Compared to specifically designed glass or ceramic nuclear waste containers, 64 cement is inexpensive, easy to manufacture, easy to formulate by mixing with other materials 65 such as blast furnace slag,¹⁴ and it benefits from centuries of use and decades of research 66 related to the civil engineering industry. This makes cement the primary candidate for large 67 volumes of low-level nuclear waste storage in post-accidental conditions. So far, most of the 68 research on irradiated cement has focused on its ability to capture radioelements, and on 69 their leaching from cement containers.^{8,15–21} As mentioned above, ⁹⁰Sr capture in cement is 70 very likely because of Ca-Sr isovalence, Ca being present in C-S-H (calcium-silicate-hydrate), 71 which is the principal binding product of cement hydration.^{22–24} Although recent atomistic 72 simulations showed that ⁹⁰Sr capture by C-S-H does not modify the elastic properties of 73 cement,²⁵ the consequences of ⁹⁰Sr transmutation via β^- decay on C-S-H structure and 74 chemical properties are still largely unknown. 75

In this work we investigate the consequences of ⁹⁰Sr transmutation in C-S-H using calcu-76 lations based on Density Functional Theory (DFT), which is an appropriate tool to account 77 for the electronic and chemical properties of the cement paste as well as those of the inves-78 tigated radionuclides. The chemical and physical mechanisms at stake in ⁹⁰Sr capture were 79 investigated by substituting Ca atoms in the atomistic model of C-S-H proposed in Refer-80 ences [26–28]. ⁹⁰Sr was then successively replaced by its daughter nucleus, ⁹⁰Y and ⁹⁰Zr, to 81 study the stability of these elements in cement paste. DFT molecular dynamics (DFMD) 82 simulations were then performed to investigate the possible chemical and structural modifi-83 cations induced locally in C-S-H contaminated by ⁹⁰Sr and its successive transmutations. 84

85 METHODOLOGY

⁸⁶ C-S-H, the principal binding phase responsible of the strength of cementitious materials, ⁸⁷ precipitates as nanoscale clusters when mixing water with di-calcium (C₂S) and tri-calcium ⁸⁸ silicate (C₃S). Given its complex structure and composition, the atomic structure of C-S-H ⁸⁹ has traditionally been based on Taylor's postulate that C-S-H is a structurally imperfect ⁹⁰ layered hybrid of two natural minerals,²⁹ tobermorite of 14 Å interlayer spacing³⁰ and

jennite.³¹ These minerals reproduce the laminar structure of C-S-H where calcium ions are 91 located between layers of silicate chains. An overview of the tobermorite and jennite-based 92 C-S-H models used in the literature is given in Refs. [32 and 33]. However, limitations of 93 these models emerged when it became possible to further characterize experimentally the 94 C-S-H molecular composition, notably the average calcium to silicon ratio (C/S = 1.7) and 95 the density of the C-S-H particle (2.6 g/cm^3) .^{34–37} These values cannot be obtained from 96 either to bermorite 14 Å $(C/S = 0.83 \text{ and } 2.18 \text{ g/cm}^3)$ or jennite $(C/S = 1.5 \text{ and } 2.27 \text{ g/cm}^3)$ 97 g/cm³). A solid solution model proposed recently³⁸ corrects most of these problems. 98

⁹⁹ The atomic structure for C-S-H used in this work has recently been proposed in order ¹⁰⁰ to bridge the gap between atomic-scale simulations and experiments.^{26–28} It is presented in ¹⁰¹ Fig. 1 and was generated following the procedure reported in Ref. [26].

102

Figure 1. (color online) Schematic representation of the C-S-H structure. Hydrogen atoms are in white, oxygen atoms in red, calcium in yellow, and Si in blue. The corner sharing SiO_4^{4-} tetrahedra forming the silicate chains are also shown.

This model was shown to reproduce accurately both the structural and chemical prop-106 erties of C-S-H. Among other properties, water content, silica chain lengths, and pair dis-107 tribution functions were compared satisfactorily to small angle neutron scattering (SANS), 108 solid-state nuclear magnetic resonance (NMR) and x-ray diffraction (XRD) experiments, re-109 spectively. The cell contains 501 atoms and has the chemical composition $Ca_{72}Si_{44}O_{235}H_{150}$, 110 with a C/S ratio of 1.64 and a density of 2.33 g/cm^3 in very good agreement with experimen-111 tal data.^{34–37} Figure 1 shows the silicate chains formed by corner sharing SiO_4^{4-} tetrahedra. 112 These chains, which form the characteristic layered structure of C-S-H, have been randomly 113 broken to obtain the desired C/S ratio.²⁶⁻²⁸ It can also be seen that the Ca²⁺ ions appear in 114 two distinct environments: intralayer and interlayer. Water, in the form of H₂O molecules 115 and OH⁻ groups, is present in the interlayer space. 116

First-principles electronic structure calculations were performed within the DFT framework using the Quantum-espresso plane-wave code.³⁹ We used the Perdew-Burke-Ernzerhof generalized gradient approximation (PBE-GGA)⁴⁰ and ultrasoft pseudopotentials with explicit semi-core electrons. The plane-wave cutoff for the Kohn-Sham orbitals was set to 80 Ry and all the calculations were performed at constant volume with a single **k**-point (the Γ -point). Residual forces on the atoms after geometric relaxation were smaller than 10^{-3} Ry/ a_0 .

We first performed a 1.2 ps DFMD simulation at 300 K to check the local stability of the C-S-H structure used. We then performed a set of DFMD simulations to study possible displacements of the substitute radioelements in the cement matrix.

Given the computational load of DFMD calculations, the latter were performed for only one of the 72 Ca sites (site number 56, interlayer, indicated in Fig. 1). These simulations were aimed at verifying that the preferred site for the substituting atoms corresponded to the site previously occupied by the Ca ion. When this was not the case, the simulations allowed us to investigate the structural modifications induced by ⁹⁰Sr insertion and decay in C-S-H.

133 **RESULTS**

¹³⁴ Substitution and decay of ⁹⁰Sr in Ca sites. C-S-H contamination was investigated ¹³⁵ by substituting one by one each Ca **atom** by Sr. The chemical effects of ⁹⁰Sr transmutation ¹³⁶ via β^- decay in C-S-H were then studied by substituting Ca with Y and Zr, successively. ¹³⁷ The C-S-H cell after substitution, denoted Ca_{n-1}X where X stands for Sr, Y or Zr, has the ¹³⁸ chemical composition Ca₇₁XSi₄₄O₂₃₅H₁₅₀. Each substitution is followed by relaxation of the ¹³⁹ atomic positions. The substitution energy $\Delta E_X(i)$ calculated with respect to the bulk ¹⁴⁰ phases of the elements at 0 K is defined as:

$$\Delta E_{\mathcal{X}}(i) = E_{\mathrm{Ca}_{n-1}\mathcal{X}}(i) - E_{\mathrm{Ca}_n} + E_{\mathrm{Ca}}^{\mathrm{bulk}} - E_{\mathcal{X}}^{\mathrm{bulk}}$$
(1)

where $E_{\text{Ca}_{n-1}X}(i)$ is the energy of the cell containing element X at site *i*, E_{Ca_n} is the energy of C-S-H before substitution, and E_X^{bulk} are the energies of the bulk phases: face-centered cubic for Ca and Sr, and hexagonal close-packed for Y and Zr. The calculated substitution energies for Sr, Y and Zr in each one of the 72 Ca sites of the simulation cell are presented in Fig. 2.

146

Figure 2. (color online) Substitution energies for (a) Sr, (b) Y, and (c) Zr (circles) in the 72 Ca sites calculated with respect to the bulk phases at OK. The vertical lines separate the first 48 sites corresponding to intralayer sites trapped between silicate chains and the remaining 24 sites (number 49 to 72) corresponding to the interlayer area. The horizontal lines stand for the average substitution energy value, calculated separately for the intralayer and interlayer.

Figure 2(a) shows the results for Sr. As expected from the isovalence between Sr and Ca, the substitution energy is generally low (0.15 eV on average), with 7 negative values. Negative $\Delta E_{\rm Sr}$ values indicate sites where Sr is more stable than Ca, and will tend to substitute it, thus contaminating the sample. To further analyze the data, we divided Fig. 2(a) into two sections marked by a vertical line: the first 48 sites correspond to intralayer Ca sites trapped between silicate chains and the remaining 24 sites (number 49 to 72) ¹⁵⁸ correspond to the interlayer area, where the Ca ions co-exists with water molecules and OH⁻ ¹⁵⁹ groups. We also show in Fig. 2(a) the average substitution energy calculated separately for ¹⁶⁰ the intra and interlayer with a horizontal blue line; the substitution energies for ⁹⁰Sr are, on ¹⁶¹ average, lower in the interlayer (0.08 eV) than in the intralayer (0.19 eV).

It is interesting to note here that due to the configurational entropy contribution to the free energy, solution energies of this order of **magnitude** imply quite a large solubility limit even at room temperature. A regular solution model with a solution energy of 0.08 eV gives, for example, a solubility at room temperature of 4%, thus providing an order of magnitude of the amount of Sr that can be incorporated into cement.

These results are in good agreement with experimental observations showing that Sr uptake in cement occurs preferably by Ca substitution in C-S-H.^{22,23} They also showed that the Sr^{2+} -Ca²⁺ exchange might occur in the interlayers of the C-S-H phases.²³ The presence of other isotopes of Sr arising from the raw materials (⁸⁶Sr and ⁸⁷Sr) in standard cement should not modify this mechanism since the quantity is negligible (approximately 0.1%).

(columns 2 to 4) and to the hydrated forms of the ions (columns 5 to 7) (eV) on all the
72 substitution Ca sites and separately on the 48 intralayer sites and on the 24 interlayer sites.

172

Table 1. Average substitution energy $\Delta E_{\mathbf{X}}$ calculated relative to the bulk phases at 0K

		Relative to the bulk phase at 0 K $$			Relative to the hydrated forms of the ions			
		Total	Intralayer	Interlayer	Total	Intralayer	Interlayer	
175	Sr	0.15	0.19	0.08	0.23	0.27	0.16	
	Y	0.05	0.11	-0.09	-3.32	-3.26	-3.46	
	Zr	2.34	2.49	2.04	-6.43	-6.28	-6.73	

In order to investigate the chemical effects of 90 Sr β^- decay on C-S-H structure, we 177 calculated the substitution energy of Y relative to the bulk phases at 0 K in all 72 Ca 178 site. The results are presented in Fig. 2(b) and the calculated average substitution energies 179 are gathered in Table 1. Fig. 2(b) shows that the substitution energy of Y is generally lower 180 than that of Sr, with a larger dispersion and an average value of 0.05 eV. Overall, 28 sites 181 substituted with Y display a negative $\Delta E_{\rm Y}$. Y is consequently more stable in C-S-H than 182 Sr, which could seem surprising because, with a theoretical charge of 3+, Y is not isovalent 183 with Ca. Nevertheless, it has been shown experimentally that other 3+ charged metals (Nd, 184

¹⁸⁵ Cm and Eu) can be accommodated by substitution of Ca in C-S-H.^{41–44} For Y, the average ¹⁸⁶ substitution energy is lower but still positive in the intralayer region (0.11 eV), and it is now ¹⁸⁷ negative in the interlayer spacing (-0.09 eV). We also notice that the difference between the ¹⁸⁸ average substitution energy in the intra and interlayer regions is larger for ⁹⁰Y (0.20 eV) ¹⁸⁹ than for ⁹⁰Sr (0.11 eV).

¹⁹⁰ The substitution energies of ⁹⁰Zr, daughter nucleus of ⁹⁰Y also through β^- decay, using ¹⁹¹ the same bulk references, are given for the 72 sites in Fig. 2(c) and Table 1. Contrary ¹⁹² to Sr and Y, the calculated energies are all positive, large and widely dispersed around the ¹⁹³ average value of 2.34 eV, which is more than one order of magnitude larger than that of Sr. ¹⁹⁴ Fig. 2(c) shows again an enhanced stability upon substitution in the interlayer relative to ¹⁹⁵ the intralayer region, while the energy difference between intra and interlayer substitution ¹⁹⁶ is the largest (0.45 eV).

The substitution energies that we presented here use the energies of the bulk phases 197 at 0 K as a reference. Another possibility would be to use the solvation energy of the 198 corresponding hydrated forms of the ions. To convert from the elemental forms to the 199 hydrated ones, one should add to the bulk energies $E_{\mathbf{X}}^{\text{bulk}}$ in Eq. (1) two positive 200 quantities, the **corresponding** cohesion and ionization energies and a negative one, the 201 hydration energy of the **corresponding** ions. Using the values reported in Ref. [45] for the 202 latter, we have found that the new reference shifts the points in Figures 2(a), 2(b), and 2(c)203 by 0.08, -3.37, and -8.77 eV respectively. With respect to the hydrated ions, the average 204 substitution energies become 0.23, -3.23, and -6.43 eV (see Table 1). 205

The most important difference is the highly negative value of the substitution energies for Zr originated by the unstable character of the hydrated forms of Zr^{4+} which has been reported to be stable only in dilute solutions with a pH below 0.⁴⁶

This is an important result meaning that substitution of Ca by Zr is unfavored when compared to the bulk phases at 0 K but the substitution is very likely when compared to the hydrated forms in water. However, in order to state a definitive conclusion on the most suitable adsorption site for Zr a systematic study of all possible compounds and coordination complex has to be performed. Such study is beyond the scope of the present paper.

Finally, we have also verified that Sr in C-S-H prefers to substitute Ca rather than Si (present in the silicate chains). Substitution energies with respect to the bulk phases obtained for Sr replacing Si are around 4 eV, which are 10 times larger than those obtained
when Sr replaces Ca, thus rendering this process extremely unlikely. This is expected from
the charge imbalance locally originated by such a substitution.

Effects of temperature on contaminated C-S-H. To further investigate the effect of 220 ⁹⁰Sr contamination and decay on the structure of C-S-H, we performed DFMD simulations 221 at 300 K for 1.2 ps. The goal of this is to investigate if the presence of Sr and its daughter 222 nuclei Y and Zr can lead to structural modifications of the cement paste, or if they are 223 likely to stay in former Ca sites as assumed above. Given the computational cost of such 224 calculations, we focused on a single Ca site, number 56 in our notation, which is situated 225 in the interlayer spacing. This site is a good candidate to test our hypotheses. Since its 226 substitution energy is average for Sr and larger than average for Y and Zr, the daughters 227 are likely to migrate. 228

For the DFMD simulations, we have used a temperature control based on velocity rescaling. In this scheme, the velocities are rescaled if the average temperature and the target temperature of the system differ in more than a certain tolerance, which here was set to 50K.

The thermal relaxation of Sr56, Y56 and Zr56 during the simulated time range was 233 investigated by studying the displacements of the three substitute atoms. The results are 234 presented in Fig. 3. The displacements were found to be rather small, not exceeding 1.5 Å, 235 as one would expect in such short simulations. Fig. 3(a) shows that Sr56 (in blue) travels a 236 maximum distance of 0.5 Å before 0.6 ps, after which it starts moving away from its original 237 position rather quickly before stabilizing again. Y56 does not move much away from its 238 original position. The maximum total displacement calculated remains under 0.5 Å over the 239 complete DFMD simulation. The displacement of Zr56 (orange) is qualitatively different 240 from Sr56 and Y56. Not only it is larger, but it increases monotonically from the start of 241 the simulation, thus suggesting that Zr is not stable in the interlayer Ca sites. 242

The distance traveled by Sr56, Y56, and Zr56 can be decomposed into the contributions along the x, y and z directions, as shown in Fig. 3(b), (c), and (d). We also show in Fig. 3 the coordination polyhedra around Sr56, Y56, and Zr56 at t = 0 ps (left) and 1.2 ps (right). Figure 3(b) shows that the large increase of distance starting at 0.6 ps in Sr56 is mainly due to displacements of equal amplitudes in the y and z directions, i.e. along the $[01\overline{1}]$ direction which is perpendicular to the silicate layers (see Fig. 1). The variations in the x direction are small after thermalization, and stabilize close to zero after 0.4 ps. The main difference in the coordination polyhedra is the elimination of one of the hydration waters.

251

Figure 3. (color online) (a) Distance traveled by Sr56 (blue), Y56 (green) and Zr56 (orange) as a function of time; and evolution of the position of (b) Sr56, (c) Y56, and (d) Zr56 with time at 300 K, along the x (plain lines), y (dashed lines), and z (dotted lines) direction. The corresponding coordination polyhedra formed by X56-O are shown at t = 0 ps and t = 1.2 ps respectively on the left and right of (b) to (d)).

The same is valid for Zr56 (see Fig. 3(d)), where the largest displacements are also along the [011] direction (see Fig. 3(d)), although in this case the displacement continues increasing over time. In consequence, the surroundings of Zr56 are modified during the simulation, the major difference being that the coordination evolves from one SiO_4^{4-} tetrahedron, two hydration waters and two OH groups at t = 0 ps to two SiO_4^{4-} tetrahedra and three OH groups at t = 1.2 ps (see Fig. 3(d)).

Figure 3(c) shows that the total displacement calculated for Y56 is due to small oscillations of this atom around its original position in the three directions, due to thermal motion, and no important modification is visible on the Y56-O polyhedron. The similarity between
the O-Ca and O-Y bond lengths (see below) is certainly at the origin of this result.

The configurations reached after 1.2 ps of DFMD simulation were relaxed back to 0 K 267 using the same convergence criterion on the total energy and forces used for the substitution 268 energy calculations. This calculation was performed in order to verify whether the ground 269 state energies obtained after the thermal rearrangement are similar to those displayed in 270 Fig. 2. Before the DFMD simulation, the Y-Sr energy difference was 0.37 eV and the Zr-Sr 271 energy difference was 2.82 eV, i.e. site 56 did not exactly respect the global trend according 272 to which Y is slightly more stable than Sr. After the 1.2 ps DFMD simulation and quenching 273 back to 0 K, we found that the substitution energy for site 56 reverts, now conforming to 274 the hierarchy previously calculated: it is lowest for Y, small for Sr and large for Zr. The 275 energy differences are now -0.05 eV for Y-Sr and 2.88 for Zr-Sr, thus validating the previous 276 approach. 277

278 DISCUSSION

Pair distribution. In order to investigate the physical origin of the relative stability of Sr, Y, and Zr in the cement paste, we calculated the pair distribution function (PDF) for the X-O bonds at 0 K (X = Ca, Sr, Y, Zr). We compare the PDF with the average bond lengths obtained by Shannon from an extensive compilation of crystallographic data.^{47,48} The pair distributions are shown as solid black lines in Figures 4(a) to (d).

The PDF for Ca-O is shown in Fig. 4(a) along with the value of 2.40 Å tabulated by Shannon for the Ca-O bond length, which is indicated by a vertical line. The average Ca-O bond length was calculated to be 2.43 Å, in good agreement with the tabulated value. These values are reported in Table 2.

The Sr-O PDF is shown in Fig. 4(b). Its maximum is shifted to larger distances compared to the Ca-O pair distribution, in good agreement with the tabulated value. The corresponding Sr-O bond length, 2.56 Å, is also close to the tabulated value of 2.58 Å. The Y-O pair distribution shown in Fig. 4(c) is shifted towards shorter distances compared to the Ca-O pair distribution. The bond length was found to be 2.36 Å, which is slightly larger than the tabulated bond length of 2.30 Å. The 0 K Zr-O bond length is the shortest (2.23 Å) and displays the largest discrepancy with the tabulated value of 2.12 Å. This can be correlated to the large substitution energies with respect to the bulk phases found for Zr in the previous section.

297

Figure 4. (color online) Pair distribution functions for the O- (a) Ca, (b) Sr, (c) Y, and (d) Zr bonds calculated on average for all sites at 0 K (black lines), for site 56 at 0 K (solid colored lines), and for site 56 at 300 K (colored dotted line). Cubic splines have been used to smooth the pair distribution functions.

The pair distributions for the intralayer and interlayer sites do not show substantial 302 differences. To illustrate this point, we report in Table 2 the average bond length for these 303 two regions. The maximum difference calculated between the intra and interlayer X-O 304 distances is 0.02 Å for Zr, which is very small compared to differences among elements and 305 hence does not explain the general preference for Ca substitution in the interlayer region. 306 In Figures 4(b) to (d) the colored lines show the pair distributions calculated for the X56-O 307 bond at two different temperatures: 0 K (solid colored lines) and 300 K, averaged over the 308 stable 1 ps part of the DFMD simulation (dashed colored lines). 309

The pair distribution for Sr56-O at 0 K (Fig. 4 (b)) is close to the average Sr-O pair distribution resulting in bond lengths that are similar (see Table 2). The same applies to the pair distributions and bond lengths calculated for site 56 replaced by Y and Zr at 0 K, thus confirming that site 56 is a good candidate to represent the average properties of these atoms in C-S-H.

Table 2. X-O bond lengths in the C-S-H structure. The first three columns report the average bond 315 length calculated on all sites (Total) and separately in the intralayer (Intra) and in the interlayer 316 (Inter) sites at 0 K. The next two columns give the X-O bond length calculated for atom X in 317 site 56 at 0 K and at 300 K. The last column gives the values obtained from Table 1 of Ref. [48] 318 (Shannon1976). For easy of comparison we consistently used the reported values for coordination 319 number VI and the formal charges 2+, 2+, 3+, and 4+ for Ca, Sr, Y, and Zr respectively. We did 320 not take into account the distortion of the coordination polyhedra or the bond length distribution. 321 All the values are given in Å. 322

			Average, 0 K		Sit	te 56	
		Tot	Intra	Inter	0 K	300 K	Shannon1976
	Ca	2.43	2.43	2.43			2.40
323	Sr	2.56	2.56	2.57	2.58	2.53	2.58
	Y	2.36	2.33	2.33	2.30	2.25	2.30
	Zr	2.23	2.23	2.21	2.21	2.15	2.12

The stability of the contaminated C-S-H structure with temperature was investigated by 325 calculating the pair distributions for the X56-O bonds on average at 300 K (dashed colored 326 lines on Figures 4(b) to (d)), and comparing them to the pair distributions obtained at 0 K 327 (solid colored lines). A general broadening of the PDF due to the temperature is visible on 328 all three figures. A slight shift to shorter distances is also observed, which results in shorter 329 average bond lengths (see Table 2). This result can be due to the ability of the mobile H_2O 330 molecules and OH⁻ groups from the interlayer to rearrange and form shorter bonds with 331 the substitutional atom under the effects of temperature. 332

Interestingly the average bond length of Zr56-O at 300K is very close to the tabulated value of 2.12 Å. In the beginning of the DFMD simulation, Zr56 is located in the interlayer spacing, surrounded by water molecules and OH^- groups. Then, Zr56 migrates under the effects of temperature so that, after 0.5 ps, two of the seven nearest O atoms belong to silicate chains (SiO₄⁴⁻ tetrahedron). Based on the latter observation and on the isovalency

of Zr with Si, it is natural to wonder whether or not it is convenient for Zr to substitute Si 338 instead of Ca atoms in C-S-H. We investigated this possibility by substituting Zr for Si in 339 seven (out of 44) sites. The calculated energies with respect to the bulk phases were 340 all negative, varying from -2.15 eV to -0.41 eV, with an average value of -1 eV. These 341 energies are much lower than the ones reported in Figure 2(c), and indicate that Zr will 342 certainly stabilize by interfering with the layered structure characteristic of C-S-H. Similar 343 conclusions have been found for the uptake of other 4+ charged metals (Np, Th)^{24,49} (Sn)⁵⁰ 344 in C-S-H. More firm comparisons however require further investigation, e.g. via DFMD 345 simulation over longer time scales using classical force fields to overcome the time-scale 346 limitations imposed by the first-principles description of the interactions. 347

Analysis of the charges. In order to analyse the bonding characteristics we have 348 calculated the Bader charges⁵¹ for the configurations relaxed at 0 K using the Bader Charge 349 Analysis tool.⁵² In this method the atomic charge is defined as the nuclear charge minus the 350 integral of the electronic density in a well-defined volume around the atom. The obtained 351 charges are systematically smaller than the expected formal charges. The more ionic the 352 bond the closer the Bader charge to the formal charge. In this way we obtained 72 values 353 of the effective charge for Ca, Sr, Y and Zr. The average effective charges for all elements 354 are reported in Table 3. 355

Table 3. Average effective charge calculated on all sites (Tot) and separately in the intralayer 356 (Intra) and in the interlayer (Inter) sites. Charge of site X56 at 0 K and 300 K. The theoretical 357 charge for each element is given for information in the first column. All charges are expressed in 358 the elementary charge unit e. 359

			Site 56		
		Tot	Intra	Inter	
360	Ca^{2+}	1.60 ± 0.04	1.59	1.61	1.60
	Sr^{2+}	1.62 ± 0.04	1.61	1.63	1.66
	Y^{3+}	2.22 ± 0.11	2.21	2.23	2.22
	Zr^{4+}	2.28 ± 0.41	2.25	2.33	2.15

Ca and Sr are found to be isovalent, as expected, with an effective charge of approximately 362 1.6e on average. This charge is close to the formal charge of these elements, which means 363

that the bonding of these systems is ionic, as expected. Y in Ca sites have an average 364 charge of 2.22e, which suggests that Y donates (on average) a large part of its valence 365 electrons, exhibiting a charge state that is intermediate between the 2+ corresponding to 366 the substituted atom, and its own ionic charge of 3+, suggesting a more covalent bonding 367 for this radio element. This results in a slightly lower substitution energy for Y than that of 368 Sr. Interestingly, Zr has an average charge of 2.28e, similar to that of Y meaning significant 369 covalency in this system. As the Zr charge in cubic ZrO_2 is 2.52e, the smaller average value 370 of the charge means that despite the energy relaxation, the substitution sites originally 371 optimized for Ca^{2+} do not have enough states available in the neighboring oxygen atoms to 372 accept more electrons. This, combined with the pair distribution analysis, could explain the 373 large substitution energies of Zr in Ca sites. 374

To understand the general preference for substitution in the interlayer we report in Table 376 3 the average effective charge calculated separately in the intra and interlayer regions. There 377 is a small but systematic increase of the Bader charges in the interlayer sites with respect to 378 the intralayer ones. This can be explained by the conspicuous presence of oxygen in the form 379 of mobile OH⁻groups in the interlayer. These can bind more easily to the substitutional 380 ions, whereas in the intralayer the neighboring oxygens belong to the silicate chains and are 381 thus less prone to accept electrons and stabilize the ions.

Finally, we note that the difference between inter and intralayer average effective charges 382 increases along the radioactive decay sequence, from ⁹⁰Sr to ⁹⁰Zr. Indeed, the difference 383 between the intralayer and interlayer average charge is the smallest for Sr and Y (around 384 (0.02e) and four times larger for Zr (0.08e). This result correlates with the substitution 385 energy difference between the intralayer and the interlayer regions that also increases along 386 the same decay sequence, as pointed out in the Results section. Similarly, the dispersion 387 around the average value is the smallest in Sr, intermediate in Y and the largest in Zr, for 388 both the substitution energies (see Fig. 2) and the Bader charges (see Table 3). 389

Environmental implications of the study. *Ab initio* calculations and DFMD simulations were performed to study ⁹⁰Sr contamination and transmutation in C-S-H, the principal binding hydration product of cement. ⁹⁰Sr and its daughter radionuclide ⁹⁰Y were found to be stable in the cement paste, with a general preference for substituting Ca in the interlayer sites, where water enhances the possibilities for atomic bonding and charge transfer. This suggests that cement could be a good material to store the intermediate-half-life fission ³⁹⁶ product ⁹⁰Sr, even in large concentrations. A mean field estimation gives a solubility limit ³⁹⁷ of the order of 4% at room temperature, i.e., three ⁹⁰Sr out of 72 Ca sites. It could be ³⁹⁸ relevant in the context of nuclear waste storage under accidental conditions, for example in ³⁹⁹ the Fukushima case where, to the best of our knowledge, a solution to the problem of storing ⁴⁰⁰ the highly concentrated ⁹⁰Sr after extraction from the emergency reactor cooling water has ⁴⁰¹ not been found yet.

The present work also showed that 90 Zr (stable daughter nucleus of 90 Y) is not stable 402 in Ca sites when the bulk phase of the corresponding elements at 0K is used as reference 403 but stable when the hydrated form of the corresponding ions is used. The low substitution 404 energies found for ⁹⁰Zr in Si sites indicate that ⁹⁰Zr could interfere with the silicate layers. 405 Consequences of this result, such as possible modification of C-S-H mechanical properties 406 by ⁹⁰Zr migration or structural damage, should be further investigated and could benefit 407 from the use of other simulation techniques such as classical force-field molecular dynamics 408 simulations that can reach time scales of microseconds, as opposed to the picoseconds that 409 can be achieved using DFMD. 410
