12	Highlights
13	• Viscoelastic creep deflection of BFRP reinforced timber beams measured over a 75-week period.
14	• No significant reduction in relative viscoelastic deflection due to FRP reinforcement.
15	• Beneficial reduction in strain on the tension face due to reinforcement.
16	• Eurocode 5 Service Class 1 creep modification factors may be suitable for FRP reinforced beams.
17	
18	ABSTRACT: An investigation was carried out to examine the effect of flexural reinforcement on the long-term behaviour
19	of timber beams. Creep tests, utilising statistically matched groups, were performed under Service Class 1 conditions on
20	reinforced and unreinforced beams loaded to a common maximum compressive stress of 8 MPa. As flexural reinforcement
21	resulted in a reduction in the timber tensile stresses, the viscoelastic tensile strains in the reinforced members were found
22	to be significantly lower than in the unreinforced beams. It was found that the viscoelastic relative creep deflection was
23	governed by the stress level in the timber and the reinforcement had an insignificant effect. It is concluded that current
24	creep modification factors in Eurocode 5 may be suitable for the design of reinforced timber elements under Service Class
25	1 conditions.

27	1 INTRODUCTION
28	Structural timber products have been shown to have benefitted with regard to stiffness and ultimate load capacity when
29	reinforced with FRP (Fibre Reinforced Polymer) materials of a superior stiffness. The short-term behaviour of these
30	reinforced elements is relatively well understood. The addition of reinforcement can delay tension failure in timber flexural
31	elements and utilise the additional capacity of the timber in the compression zone resulting in much more consistent

behaviour as well as a significant increase in flexural stiffness [1–9]. However, the long-term or creep behaviour of such members has received less attention. Accurate prediction of the long-term performance of timber elements is of crucial importance to structural engineers when designing timber structures as timber is particularly susceptible to large creep deformations when stressed for long periods of time.

36 Creep effects in timber elements can be divided into two main categories, namely, viscoelastic creep and mechano-37 sorptive creep. The viscoelastic creep component is defined as the deformation with time at constant stress and under 38 constant environmental conditions, which is typical of indoor conditions. Under variable environmental conditions, 39 additional mechano-sorptive creep and swelling/shrinkage behaviour occurs. The mechano-sorptive creep effect has been 40 shown to dramatically accelerate the rate of creep in a loaded timber element and is defined as a deformation due to the 41 interaction between stress and moisture content change due to variable environmental conditions [10–13]. Eurocode 5 [14] 42 provides modification factors which allow design engineers to account for both viscoelastic and mechano-sorptive creep 43 behaviour of solid timber members and engineered wood products. Currently, there are no guidelines on how to account 44 for the influence of reinforcement on the creep response of reinforced timber elements. The reasons for this are partly due to a lack of knowledge, particularly related to the long-term performance of such reinforcement systems. To date only a 45 46 small number of studies have investigated creep behaviour in reinforced timber and further work in this area is required to 47 enable the development of harmonised design rules for structural engineering applications. This paper focuses on 48 establishing the influence of reinforcement on the viscoelastic creep of reinforced timber beams.

49 *1.1* Viscoelastic Creep Behaviour of Timber

50 For many structural applications, the most important mechanical property of timber is its resistance to deflection, including 51 both elastic and creep deflection. The contribution of creep deflection to the total deflection is generally much more 52 significant in the case of timber structures to those made of steel or concrete. The creep behaviour of timber also more 53 complex as it is a function not only of timber but also environmental conditions, which change the moisture content of the 54 material. When stressed in a constant climate condition, a timber element undergoes an instantaneous elastic deflection 55 followed by viscoelastic creep behaviour with time. Under this constant climate condition, the level of viscoelastic creep 56 depends on the stress level, temperature and moisture content of the timber. Senft & Suddarth [15] examined small 57 specimens (41.3 x 50.8 x 203.2 mm³) of Sitka spruce (Picea sitchensis) under compression load at stress levels of 10, 20, 58 40 and 60% of ultimate strength for load durations up to twenty days. The moisture content remained constant throughout 59 to exclude the mechano-sorptive effect and focus solely on viscoelastic creep. They found that the viscoelastic creep 60 behaviour increases with increasing stress levels and significantly, they found that creep deformation can occur at stress

61 levels as low as 10% of ultimate strength. It was also reported that, at higher stress levels (>55%), specimens are susceptible 62 to creep rupture resulting in failure [15,16]. Similarly, an increase in temperature has been shown to result in higher 63 viscoelastic creep deformations. Davidson [17] performed creep tests on three different species at a series of constant temperatures. It was shown that the rate of creep increased slightly with increasing temperature from 20 °C to 50 °C. The 64 magnitude of viscoelastic creep has been also shown to depend on the moisture content of the timber [10,11,18]. In a study 65 66 by Hering and Niemz [19], the viscoelastic behaviour of European beech timber elements subjected to four-point bending 67 was investigated and the longitudinal creep compliance at three different moisture contents (8.14%, 15.48% and 23.2%) was examined. Each timber specimen was loaded to approximately 25% of the ultimate bending strength for a period of 68 69 approximately 200 hr and the viscoelastic creep behaviour was found to increase linearly with increasing moisture content. 70 Another study designed to examine if the rate of creep eventually decreases towards a creep limit was performed by Hunt 71 [20]. Experimental creep tests on solid timber elements were carried out in a carefully controlled environment over a 13-72 week period. Creep functions were matched to these experimental test results and to creep test results by Gressel [21] over 73 a much longer period of time (8 years). The curves were extrapolated to estimate the viscoelastic creep after 50 years under 74 sustained load. No evidence was found to suggest a viscoelastic creep limit exists in timber when stressed in a constant climate condition. This demonstrates the potential for timber elements to deform throughout their service life and 75 76 demonstrates the importance of understanding its behaviour.

77 1.2 Viscoelastic Creep Behaviour in Reinforced Timber

78 When timber elements are reinforced, the behaviour of the elements can be greatly altered. The short-term or instantaneous 79 elastic behaviour of reinforced elements has been investigated by many authors and significant improvements in stiffness 80 and ultimate moment carrying capacity have been demonstrated [1,3,7–9,22]. More ductile behaviour can be achieved 81 when modest proportions of reinforcement are utilised in strategic locations. Reinforcing the tension zone of timber 82 elements can delay tension failure and utilise the additional capacity of the timber in the compression zone. A limited number of studies have focused on the long-term or viscoelastic creep behaviour of FRP reinforced timber elements. Plevris 83 84 and Triantafillou [23] performed long-term creep tests on carbon fibre reinforced polymer (CFRP) reinforced beams under 85 three-point bending. There was a relatively small sample size of three beams, one unreinforced control beam and two reinforced beams with two different area reinforcement ratios of 1.18% and 1.65%, respectively. The tests were carried out 86 87 under constant climate conditions and similar loads were applied to each beam. This resulted in different stress levels in 88 the timber. It was determined from the experimental results, that the creep behaviour of the FRP-reinforced timber elements 89 was primarily dominated by stress within the timber.

90 In a study by Yahyaei-Moayyed and Taheri [24], the creep performance of southern yellow pine (SYP) and Douglas fir 91 (DF) timber beams reinforced with aramid fibre reinforced polymer (AFRP) was examined. These creep tests were carried out in an uncontrolled climate over a period of 800 hours and it is noted that the applied loads (P) were not the same for 92 93 the unreinforced and reinforced beams. When comparing one SYP unreinforced (P = 4.85 kN) with one SYP reinforced 94 beam (P = 4.40 kN) there appeared to be a reduction in creep deflection, but it was not clear if this reduction was due to 95 different stress levels within the timber or the presence of the AFRP reinforcement. The reduced load on the reinforced 96 beam led to a lower stress level within the timber when compared to the unreinforced beam making comparisons difficult. Interestingly when one unreinforced DF beam (P = 5.60 kN) and one reinforced DF beam (P = 5.76 kN) were compared, 97 98 there was a slightly higher load on the reinforced beam and a similar creep deflection was observed. The timber stress 99 levels in both the unreinforced and reinforced beams were more comparable in this case. There was also an influence of the uncontrolled climate condition in this study and possible swelling/shrinkage or mechano-sorptive creep deformations 100 101 as a result of the minor fluctuations in moisture content.

102 Davids et al. [25] performed long-term creep tests on six unreinforced and six reinforced 7 m long Douglas fir and 103 western hemlock glulam beams in a sheltered environment with controlled temperature and uncontrolled relative humidity. 104 A proportion of the beams were reinforced with glass fibre reinforced polymer (GFRP) plate with two percentage area 105 reinforcement ratios, namely, 1.1% and 3.3%. While the laboratory tests demonstrated the effectiveness of the GFRP 106 reinforcement in reducing the elastic deformation between the unreinforced beams and the reinforced beams, a difference 107 between the creep deformation of the unreinforced elements and the GFRP reinforced elements is only seen at the higher 108 reinforcement level. It is noted by Davids et al. [25] that the effectiveness of FRP reinforcement on reducing creep cannot 109 be inferred from the test data due to the different load and associated stress levels in the timber in addition to the 110 uncontrolled relative humidity during the test.

The creep behaviour of a loaded timber element has been shown to be heavily influenced by the stress level within the timber. When reinforced, the flexural stiffness of the timber beam is altered and stress distribution through the cross-section is affected. In an effort to reduce the difference in stress distribution between unreinforced and reinforced beams, beams should be loaded to a common maximum stress, similar to that performed by Kliger et al. [22] who carried out mechanosorptive creep tests on beams loaded to a common maximum compressive stress.

116 *1.3* Objectives of the Current Study

117 The objective of this study is to investigate the influence of flexural reinforcement on the long-term viscoelastic behaviour 118 of timber beams in a constant climate. As has been shown, the viscoelastic behaviour of timber is influenced by many

119 factors such as the timber mechanical properties, moisture content, temperature and the stress level in the timber. To 120 characterise the influence of the reinforcement on the viscoelastic response, a test procedure was designed to minimise the 121 differences in timber properties, environmental conditions and stress level between unreinforced and reinforced beam 122 groups. Groups of beams with statistically matched flexural stiffness were tested in a customised test rig in a constant 123 climate over a 75-week period. Different loads were applied to the reinforced and unreinforced beams to minimise the 124 difference in bending stress levels. This provides a common basis for comparative studies. The findings of this study are 125 intended to contribute to the database of knowledge required to develop future design guidelines for reinforced timber 126 beams.

127 2 EXPERIMENTAL PROCEDURE

128 2.1 Introduction

The glued laminated beams used in the test programme were manufactured using Irish-grown Sitka spruce. The lay-up of each glued laminated beam was designed to allow beams of approximately equal stiffness to be manufactured. A proportion of the beams were reinforced with basalt fibre reinforced polymer (BFRP) rods in the bottom tensile lamination. These unreinforced and reinforced beams were subject to short and long-term flexural testing in a controlled, constant environment.

134 2.2 Glulam Materials and Manufacture

The Sitka spruce timber used in this study was grade C16. Sourced in Ireland, this timber has an average rotation length of 135 30 - 40 years [26] and is characterised as a fast-growing, low-density timber which when subjected to flexural loading 136 generally fails in tension due to the presence of knots [3,27]. However, when combined to create a composite element such 137 138 as a glued laminated beam, the capacity of this softwood timber may be greatly increased [5,7]. Each lamination was 139 strength graded using a mechanical grading machine and ranked in descending order of modulus of elasticity. The lay-up 140 of forty beams was designed using the machine grading results and manufactured in the Timber Engineering Laboratory 141 at the National University of Ireland, Galway. The design process minimised the variation in mean modulus of elasticity 142 of all forty beams. The beams were laminated by applying a 1:1 phenol resorcinol formaldehyde adhesive and clamping to a pressure of 0.6 N/mm² for 24 hours in accordance with EN 14080 [28]. The beams comprise four laminations with each 143 144 beam measuring approximately 98 mm x 125 mm x 2300 mm. Each beam was conditioned in a constant climate condition 145 at a temperature of 20 ± 2 °C and at a relative humidity of $65 \pm 5\%$, prior to reinforcement.

146 BFRP reinforcement was chosen as a suitable material to reinforce the timber beams. This novel material has received 147 less attention in previous studies but has the potential to rival more commonly used fibres in load bearing applications in the construction industry [29-32]. Twenty of the beams were reinforced with two 12 mm BFRP rods positioned in two 148 149 circular routed grooves in the bottom tensile lamination. The grooves were sized to accommodate the BFRP rod plus a 2 150 mm glue line, as seen in Fig. 1. A two-part structural epoxy adhesive was used to bond the reinforcement to the timber. 151 The BFRP rod manufacturer reported a tensile strength of 1000+ N/mm² and a modulus of elasticity of 45+ GPa [33] but 152 experimental tensile tests on six test specimens in accordance with ISO 10406-1 [34] demonstrated a mean tensile strength of 905 N/mm² and a mean modulus of elasticity of 50.7 GPa. The beams were placed a conditioning chamber with a 153 154 temperature of 20 ± 2 °C and with a relative humidity of $65 \pm 5\%$, where they remained to cure for a period of 3 weeks 155 prior to flexural testing.

156

157 Fig. 1. Cross-section of a Sitka spruce manufactured beam reinforced with two BFRP rods in the tensile lamination.

158 2.3 Short-term Testing

Each beam underwent a short-term four-point bending test in accordance with EN 408 [35] to evaluate the flexural stiffness. The load was applied through a hydraulic actuator at a rate of 0.15 mm/s to a maximum load of approximately 40% of the ultimate failure load to ensure that the elastic limit was not exceeded. The deflection at the midspan of the beam was measured using two LVDTs, one for determining the local stiffness and the other for the global stiffness.

This short-term test was performed on all beams in their unreinforced state to determine their initial flexural stiffness. The test results allowed two groups, statistically equal in terms of bending stiffness, to be created. One group was subsequently reinforced. The creation of matched groups reduces the difference in the beams due to the variability inherent within timber and provides a reliable basis for comparative studies. Once reinforced, the four-point flexural test was 167 repeated. The test set-up remained the same throughout allowing the percentage increase in bending stiffness to be 168 calculated.

169 2.4 Long-term Testing

170 2.4.1 Test Frame Design and Instrumentation

There is no standardised method for examining the creep behaviour of timber beams. As a result, different test methods and test frames have been reported in the literature. The majority of authors implement a four-point bending test set-up [13,22,24,25,27]; however, in some cases, a three-point bending test set-up [23] or a uniformly distributed load across the whole length of the member have been used [36].

175 In this study, the creep test frame was designed to implement a four-point flexural test set-up. The geometrical constraints 176 of this set-up were in accordance with the short-term flexural test prescribed in EN 408 [35]. The creep test frame was 177 designed to accommodate eighteen beams simultaneously loaded to a constant bending stress to induce viscoelastic creep 178 behaviour with time. The constant bending stress is achieved by applying a dead load, M (steel plates 250 x100 x 10 mm³), 179 through a lever-arm mechanism. An example of this mechanism on a single beam can be seen in Fig. 2. The lever-arm is 180 free to rotate about the fulcrum. The lever-arm length, a₂ (distance from the load to the fulcrum), is adjustable and dead 181 load, M, can be added or subtracted as necessary to achieve a desired bending stress. The flexural load, F, applied at a 182 distance a_1 from the fulcrum is equal to the dead load, M, multiplied by the ratio a_2/a_1 .

183

184 Fig. 2. Creep test beam loaded in four-point bending using an adjustable lever-arm mechanism.

185 The beam mid-span deflection was measured using a Mitutoyo displacement dial gauge with an accuracy of 0.01mm and 186 the mid-span longitudinal strain on the tension and compression faces was measured using electrical resistance strain gauges (TML type PLW-60-11) specially designed for long-term use on timber elements. The strain gauges on the tension
face of the reinforced beams were adhered to the timber surface of the beam situated between two routed grooves which
house the BFRP rods as seen in Fig. 3.

190

191 Fig. 3. Strain gauge orientated longitudinally between two BFRP rods on the tension face of a reinforced beam.

These long-term strains were monitored using a Campbell Scientific data acquisition system, which recorded strains every five minutes during the early stages of the test. This frequency was slowly reduced with time to its current frequency of one hour. The beams are tested in a controlled climate chamber at a temperature of 20 ± 2 °C and at a relative humidity of 65 ± 5% throughout, which coincides with Service Class 1 conditions as defined in Eurocode 5 [14].

196 2.4.2 Loading Procedure

As the aim of the tests is to determine the influence of the reinforcement on the creep performance, the applied loading for the tests was chosen to minimise the difference in the timber stress levels between the unreinforced and reinforced beams. Two different loading scenarios were investigated: the beams are loaded to the same maximum compressive stress level (Case A) or to the same load level (Case B). Analytical modelling of the stress distribution in the unreinforced and reinforced beams was undertaken assuming linear elastic behaviour. For the analysis, it was assumed that elastic moduli of the timber laminations and the BFRF rods were 8000 N/mm² and 50000 N/mm², respectively.

203 For Case A, it was assumed that each beam was loaded to a maximum compressive bending stress of 8.0 N/mm². For the 204 reinforced beam, the load required to achieve this maximum compressive stress was 6333 N as seen in Table 1. For this 205 load, the maximum timber tensile stress is 7.08 N/mm². The maximum tensile stress in the unreinforced beam is 8.00 206 N/mm², which is 13% higher than the reinforced beam. For Case B, a load of 6333 N applied to the unreinforced beam 207 results in maximum tensile and compressive timber stresses of 8.75 N/mm², which are higher by 23.6% and 9.3%, 208 respectively, than the corresponding stresses in the reinforced beam, as shown in Table 1. As the differences in the stress 209 distributions is smaller for Case A, it was decided to apply a maximum bending stress of 8 MPa on the compression face 210 of each beam in the test programme. The applied load chosen corresponds to approximately 25-30% of the ultimate load of the unreinforced glued laminated beam which was chosen to produce measurable deflections in a reasonable time scale without causing failure in the specimen. This common maximum stress level is an essential component of this test procedure as it minimises the influence of stress distribution on the long-term response of both the unreinforced and reinforced beams. This allows for comparisons to be made between creep in unreinforced and reinforced beams and the influence of the BFRP reinforcement to be quantified. To achieve this common maximum stress level, different loads were required for each beam with greater loads on average required on the reinforced beams.

217	Table 1.	Comparison	between	maximum	tensile and	compressive	timber stresses
-----	----------	------------	---------	---------	-------------	-------------	-----------------

Beam State	Load (N)	Max. Tensile Stress (N/mm ²)	Percentage Increase (%)	Max. Compressive Stress (N/mm ²)	Percentage Increase (%)
Reinforced	6333	7.08	0.0%	8.00	0.0%
Unreinforced (Case A)	5792	8.00	13.0%	8.00	0.0%
Unreinforced (Case B)	6333	8.75	23.6%	8.75	9.3%

218

219

220

221

Fig. 4. Creep test frame: (a) Loaded creep test frame in a constant climate condition at a temperature of 20 ± 2 °C and at a relative humidity of $65 \pm 5\%$, (b) Creep test beam loaded in four-point bending.

The short-term flexural test results provided stiffness values for each beam and the required load for each beam was determined using the linear elastic model. Mean vertical loads of approximately 6241 N and 5748 N were applied to the reinforced and unreinforced beams, respectively. Each beam is loaded in four-point bending separately through individual lever arms as seen in **Fig. 4(a)** and **Fig. 4(b)**. The instantaneous elastic deformation is recorded for each beam and the creep deflection results are then recorded at regular intervals with time.

229 2.5 Statistical Methods

Statistical methods have been implemented to create the matched groups described above using the test results for all beamsprior to reinforcement. Once reinforced, similar statistical methods were utilised to examine the influence of the

232 reinforcement on both the short- and long-term behaviour of the reinforced beams. Student's t-tests were carried out to 233 compare the means of each matched group to one another. When performing a Student's t-test, each sample or group being 234 compared should follow a normal distribution and the variance of each sample or group must be considered. Shapiro-Wilk tests were performed on each group to assess normality. The null hypothesis of this test assumes the sample is normally 235 236 distributed and a p-value greater than the chosen significance level indicates that the hypothesis that the data came from a 237 normally distributed sample cannot be rejected. Once normality or a normally distributed sample cannot be rejected, 238 Levene's test was performed to examine the homogeneity of the group or sample variances. Levene's test is an inferential 239 test statistic implemented to assess the equality of variances for two or more groups or samples. The null hypothesis of this 240 test assumes the sample variances are equal. If the p-value is greater than the chosen significance level, the null hypothesis 241 is accepted and it is concluded that there is an insignificant difference between the variances of all samples tested. In this study, all statistical tests are carried out to a significance level of 0.95 ($\alpha = 0.5$). In each sample studied, normality could 242 243 not be rejected and each group was assumed to follow a normal distribution. When comparing groups using Levene's test, 244 a proportion of the groups had equal variances and a proportion had unequal variances. For equal variances, Student's t-245 test was implemented as it assumes equal variances. In the case of unequal variances, an adapted version of Student's ttest known as Welch's t-test or unequal variances t-test was used to compare the means of both groups. 246

247 3 EXPERIMENTAL TEST RESULTS

248 3.1 Short-term Test Results

249 The mean flexural stiffness results and associated standard deviation for beams in their respective groups in an unreinforced 250 state are presented in Table 2 and Fig. 5. The mean local and global flexural stiffness of the Unreinforced Group are 1.40x10¹¹ Nmm² and 1.28x10¹¹ Nmm², respectively, and the mean local and global flexural stiffness of the Reinforced 251 Group are 1.46x10¹¹ Nmm² and 1.36x10¹¹ Nmm², respectively. Statistical Student's t-tests have demonstrated that there is 252 253 no evidence to suggest the mean of each group is not equal. The reinforced group was then reinforced and the short-term 254 test results for the reinforced beam group are presented in Table 3. The mean local and global bending stiffnesses for beams in their unreinforced and reinforced states are given together with the associated standard deviations. The percentage 255 256 increase in stiffness is also determined. A mean increase in local bending stiffness of 16.30% for a moderate percentage 257 reinforcement ratio of 1.85% was observed. There was a mean increase of 8.8% in global bending stiffness. There is a significant standard deviation of 5.9% associated with this global stiffness measurement. 258

266 3.2 Long-term Test Results

The long-term deflection and strain measurements over a 75-week test period are presented. Eighteen beams (nine reinforced and nine unreinforced) were tested under a common maximum compression stress in a controlled constant climate. The long-term deflection test results are expressed in terms of both total deflection and relative creep (C_R) deflection, which is defined as the deflection at time *t*, expressed as a proportion of the instantaneous elastic deflection as seen in Equation (1) [37].

$$C_R(t) = \frac{w(t)}{w_0} \tag{1}$$

273 where C_R = relative creep, w_0 = instantaneous deflection and w(t) = deflection at time, t.

As mentioned previously, for serviceability limit state design, Eurocode 5 [14] provides deformation modification factors (k_{def}) for different service classes in order to account for creep effects. The service classes correspond to predefined environmental conditions and the k_{def} factor is used to increase the instantaneous elastic deflection of the designed element to account for creep effects. Equation (2) describes the relationship between k_{def} and relative creep.

$$k_{def}(t - t_0) = \frac{w(t) - w(t_0)}{w(t_0)} = C_R(t) - 1$$
(2)

278

The total measured long-term strain results comprise the instantaneous elastic strain due to the application of the dead load and the viscoelastic creep strain with time as shown in Equation (3).

$$\mathcal{E}_T = \mathcal{E}_e + \mathcal{E}_{ve} \tag{3}$$

281

282 where ε_T = total measured strain, ε_e = elastic strain and ε_{ve} = viscoelastic strain.

Assuming linear behaviour, the viscoelastic strain component is found by subtracting the instantaneous elastic strain component from the total measured strain. The mean total measured strain data and viscoelastic strain data for the unreinforced and reinforced beams over the 75-week test period are presented.

286 3.2.1 Long-term Deflection Results

The unreinforced beam group consists of nine beams, seven of which, are monitored with displacement dial gauges. The mid-span deflection for these seven beams are given in **Fig. 6**. Beam 27 (9.068 mm) and Beam 34 (6.674 mm) have the highest and lowest total deformation (instantaneous elastic deformation + viscoelastic creep deflection) after 75 weeks, respectively. This is as expected as they have the lowest and highest bending stiffness, respectively, when measured during short-term flexural tests.

292

Fig. 6. Unreinforced deflection results.

10.0

The reinforced beam group consists of nine beams. Seven of these beams are monitored with displacement dial gauges. 293 294 The mid-span deflection for these seven beams are given in Fig. 7. Beam 30 (8.022 mm) and Beam 26 (6.072 mm) have the highest and lowest total deflection after 75 weeks, respectively. Beam 30 and Beam 26 also had the lowest and highest 295 296 bending stiffness, respectively, when measured during short-term flexural tests. The variability in the total deflection results 297 within each matched group can be seen in Fig. 6 and Fig. 7. The average unreinforced bending stiffness of each group was shown to be statistically equal from short-term test data. To compare the deflection results of the unreinforced and 298 299 reinforced groups and observe the effect of reinforcement, the average deflection for each beam group is shown in Fig. 8. After 75 weeks, the mean total deflection in the unreinforced beam group (8.032 mm) is 10.69% greater than the reinforced 300 beams group (7.219 mm). 301

302

303 **Fig. 8.** Unreinforced and Reinforced group average deflection results.

Fig. 9 presents the average relative creep deflection results with time for the unreinforced and reinforced groups. Although there is a reduction in the overall deflection in the reinforced beam group due to the FRP reinforcement (10.69%), very similar creep behaviour is observed between the measured relative creep deflections of both groups. This indicates that the reduction in total deflection observed in the reinforced group is primarily due to the lower instantaneous elastic deflection due to the increased stiffness provided by the reinforcement. The mean relative creep deflections and corresponding standard deviations of both groups are also plotted in **Fig. 9** at a series of time points over the test period. For clarity, the results of the unreinforced and reinforced groups at the similar time points are offset from one another. Statistical Student's t-tests were performed at a series of time points throughout the test and the results are presented in **Table 4**.

312

Fig. 9. Unreinforced and Reinforced average and standard deviation results at a series of time points throughout the 75-week test
 period.

The percentage difference between the mean relative creep results of the unreinforced and reinforced group show that this 316 317 difference is increasing with time. During the initial weeks (Week 0 to Week 19) the trend indicated a significant difference 318 in the creep behaviour of unreinforced and reinforced beams was developing as seen in Table 4; however, this period was 319 associated with a relatively high rate of creep deformation and after this point the statistical tests indicate an insignificant 320 difference between the mean results of both groups. Although after 75 weeks of creep testing there is a reduction in the 321 total deflection (10.69%) in the reinforced group, there is less than 1.30% difference between the mean relative creep 322 deflections of both groups at the same time point. A statistical analysis of the group means has shown that there is no 323 statistically significant reduction in viscoelastic creep deflection in FRP reinforced beams when compared to unreinforced 324 beams under similar bending stresses and constant climate conditions.

325 **Table 4.** Average relative creep deflection (standard deviation) of the unreinforced and reinforced groups at a series of time points.

327 3.2.2 Long-term Strain Results

The longitudinal strain has been measured on the tension and compression faces of seven unreinforced and seven reinforced beams. The mean total strain measurements from the tension and compression faces of the unreinforced and reinforced beam groups are presented in **Fig. 10**. The strain gauge measurements on the compression faces are similar when both beam groups are compared. The reinforced beam group experiences slightly less strain than the unreinforced beam group. In contrast, the difference between the strains measured on the tension face of each beam group is more significant. The reinforced beams experience 24.5% less strain on average after 75 weeks. This difference is as a result of the rod reinforcement and its position within the tensile lamination of each reinforced beam.

336 Fig. 10. Mean total strain results on the tension and compression face of the unreinforced and reinforced beam groups ($\varepsilon_T = \varepsilon_e + \varepsilon_{ve}$). 337 To isolate the viscoelastic strain, the instantaneous elastic strain component has been subtracted from the total strain 338 component of each individual beam. The mean viscoelastic strain results are presented in Fig. 11. Similar mean strains are 339 observed on the compression faces of both the unreinforced and reinforced beams groups indicating a similar stress and 340 creep rate within both beam groups. In comparison, the mean strains on the tension face are larger for the unreinforced 341 group than the reinforced group. The presence of the reinforcement causes a reduction in the timber tensile stresses as seen in and therefore a lower creep rate is expected (Table 1). It is important to note that the controlled climate chamber 342 remained at a constant temperature of 20 ± 2 °C and at a constant relative humidity of $65 \pm 5\%$ throughout the duration of 343 344 the test and that there was no additional effects due to mechano-sorptive creep or swelling/shrinkage of the timber.

347 Fig. 11. Mean viscoelastic strain ($\mu\epsilon$) results on the tension and compression face of the unreinforced and reinforced beam groups (ϵ_{ve}). 348 To examine the significance of differences in viscoelastic strain on the compression face, the values at a series of time 349 points are presented in Fig. 12 and Table 5. The mean viscoelastic strain results in Fig. 12 show similar trends in both the 350 unreinforced and reinforced groups. Again, there is a slightly higher standard deviation associated with the unreinforced group beams. In Table 5, the difference between the mean of each group is not statistically significant at any point 351 352 throughout the test. The percentage difference ranges from 8.23% at week 3 to a maximum of 20.80% at week 67. The 353 trend is generally increasing throughout the test; however, there is no evidence to suggest the mean viscoelastic strain 354 measured on the compression face of the unreinforced and reinforced groups is different. This shows that a similar bending 355 stress on the compression face results in a similar creep rate within the timber.

356

Fig. 12. Mean and standard deviation of the viscoelastic strain ($\mu\epsilon$) measured on the compression face of the unreinforced and reinforced groups at a series of time points (ϵ_{ve}).

360 **Table 5.** Average viscoelastic strain (standard deviation) on compression face of unreinforced and reinforced groups at a series of time points (ε_{ve}).

363 The standard deviation associated with the viscoelastic strain measurement on the tension face at a series of time points 364 can be seen in Fig. 13. The reinforced beams experience much more consistent viscoelastic behaviour and there is a greater 365 standard deviation observed within unreinforced beams. In Table 6, a comparison is made between the mean viscoelastic 366 strain component on the tension face of unreinforced and reinforced beam groups. It can be seen that even after 3 weeks of 367 testing, a percentage difference of 39.84% exists between the viscoelastic strain measured on the tension faces of 368 unreinforced and reinforced beams. Statistical Student's t-tests have shown that, at this point, the percentage difference is 369 not statically significant. The difference is not statistically significant until after week 15 with a percentage difference of 370 44.90%. This percentage difference continues to increase to a maximum of 54.33% at week 71 as seen in Table 6 and is 371 still increasing with time. This indicates a reduced creep rate on the tension faces of reinforced beams as a result of the 372 reinforcement.

381 4 SUMMARY AND CONCLUSIONS

The short-term behaviour of FRP-reinforced timber beams has been widely investigated. This study focuses on the longterm behaviour of these elements and investigates the influence of the reinforcement on the viscoelastic creep response. A test procedure has been designed to ensure that other factors known to influence the creep behaviour of timber elements do not prevent valid comparisons between the response of reinforced and unreinforced beams. These factors are the differences in mechanical properties of the timber due to the natural variability in timber properties, differences in moisture content and temperature due to the climatic conditions and differences in the stress level due to the applied loads.

388 The variability in the timber properties has been minimised by creating matched groups, statistically equal in terms of 389 unreinforced bending stiffness. The climate conditions throughout the test remained at a constant temperature and relative 390 humidity. As a result, additional moisture content, temperature, mechano-sorptive creep and swelling/shrinkage effects 391 were avoided. Each beam was subjected to a specific applied load to induce a bending stress of 8 MPa on the compression 392 face. This ensured that the timber stress levels in both the unreinforced and reinforced beam groups were closely matched. 393 Preliminary short-term flexural tests on twenty glued laminated beams demonstrated that the addition of BFRP rod 394 reinforcement in modest quantities can greatly increase the short-term flexural stiffness of glued laminated beams. An 395 average increase in local bending stiffness of 16.3% was observed for a moderate percentage reinforcement of 1.85%. The 396 results demonstrated the suitability of this material for timber reinforcement applications.

397 The long-term deflection results have shown an overall decrease in the total deflection (elastic deflection + viscoelastic 398 deflection) of reinforced beams due to the FRP reinforcement. However, when examining the long-term creep deflections, 399 it has been shown that there is no statistically significant reduction in relative viscoelastic creep deflection when comparing 400 both the unreinforced and reinforced beam groups loaded to a common maximum compressive bending stress. The 401 influence of the reinforcement on the total creep response is indirect and is due to an increase in elastic stiffness. This 402 indicates that the current creep modification factors provided for solid or engineered wood products in Eurocode 5 [14] 403 may be adequate in describing the creep behaviour of FRP reinforced beams under Service Class 1 conditions. The final 404 deflection of FRP-reinforced timber beams may be calculated using the current Eurocode 5 procedures using the composite 405 elastic stiffness of the reinforced beam. While this finding is valid for the current test programme, additional work is 406 required to determine its validity in general. The influence of the timber species, FRP material and reinforcement 407 percentage on the creep deflection behaviour requires further study. For other service class conditions, the influence of different timber moisture contents also requires investigation. Additionally, the applied stress level requires attention and the creep response at higher stress levels should be examined so that the cut-off point in relation to tertiary creep can be determined. The viscoelastic behaviour of unreinforced timber elements has been shown to be susceptible to tertiary creep or creep rupture at stress levels in excess of 55% [15,16]. The use of FRP materials may delay the onset of creep rupture and should be examined.

The viscoelastic mid-span longitudinal strains on the compression faces of both the unreinforced and reinforced beams were similar and no statistically significant difference was observed, as expected from the experimental design. In comparison, on the tension face, a statistically significant reduction in viscoelastic strain in the reinforced group relative to the unreinforced group was found. This reduction in strain rate is due to the change in the stress distribution within the timber when reinforced.

The methodology described in this paper is being used to investigate the influence of other climatic conditions. Two matched groups (one unreinforced and one reinforced) are under creep testing in a controlled variable climate condition to examine and quantify the effect of FRP reinforcement on mechano-sorptive and swelling/shrinkage behaviour of timber elements, which occurs under Service Class 2/Service Class 3 conditions with changing moisture content. This will be reported in a future publication.

423 ACKNOWLEDGEMENT

This work has been carried out as part of the project entitled 'Innovation in Irish Timber Usage' (project ref. 11/C/207) funded by the Department of Agriculture, Food and the Marine of the Republic of Ireland under the FIRM/RSF/COFORD scheme. The authors would also like to thank ECC Teo. (Earrai Coillte Chonnacht Teoranta) for supplying the timber used in this project. The contribution of the technical staff of the College of Engineering and Informatics, NUIG, in particular, Peter Fahy, Colm Walsh and Gerard Hynes, is acknowledged.
