Quantum field theory is completely characterized by the field correlations between spacetime points. In turn, some of these can be accessed by locally coupling to the field simple quantum systems, a.k.a. particle detectors. In this work, we consider what happens when a quantum-controlled superposition of detectors at different space-time points is used to probe the correlations of the field. We show that, due to quantum interference effects, two detectors can gain information on field correlations which would not be otherwise accessible. This has relevant consequences for information theoretic quantities, like entanglement and mutual information harvested from the field. In particular, the quantum control allows for extraction of entanglement in scenarios where this is otherwise provably impossible.

Introduction— The relationship between effects and causes is foundational to our everyday experience and is rooted in the basic laws of physics as we presently understand them. Both in classical and quantum physics, events happen in a fixed causal order.

One of the more intriguing proposals put forward in recent years, is that quantum physics may admit non-classical causal structures where the order of events is indefinite [1–4]. Apart from advantages afforded in computation [5, 6] and communication [7–11], the incorporation of this idea into the foundations of physics may provide new insights toward realizing a quantum theory of gravity [1, 12, 13]. This idea has become known as “Indefinite Causal Order”, or ICO.

Recently a scenario featuring an indefinite causal order of events has been experimentally realized in the form of a quantum switch [14–16]. In this setting the order in which two quantum operations A and B are performed on some target is coherently controlled by a quantum system, placing the order of operations in temporal superposition [17]. An ordinary quantum circuit using the same number of operations cannot reproduce the effects of the quantum switch [2, 5].

Little is known about how ICO affects quantum entanglement, particularly entanglement of quantum fields. The vacuum state of a free quantum field has long been known to contain correlations between timelike and spacelike separated regions [18, 19], and it is of foundational interest to understand how such correlations are affected by ICO. Vacuum correlations are at the core of the black hole information paradox [20, 21] and its pro-

posed solutions [22–24], and play a key role in quantum energy teleportation [25, 26].

Furthermore, this vacuum entanglement can be extracted from the field by swapping it with (originally separable) detectors. This procedure is called Entanglement Harvesting [27–30], and is most easily analysed by considering the detectors to be 2-level systems (qubits) each with a ground and excited state. These objects are called Unruh-de Witt (UDW) detectors.

In relativistic physics, the causal order between events is constrained by the light cones at each space-time point. In the case in which we probe the field via UDW detectors, their interaction with the field constitutes an event. Traditionally, UDW detectors are assumed to probe the quantum field at fixed space-time points, so that all events happen in a definite causal order. Our ability to, e.g., harvest entanglement from the vacuum is constrained by this fact.

In this letter, we consider what happens when a quantum-controlled superposition of two UDW detectors is used to probe the correlations of a scalar field vacuum. Specifically, a single qubit controls the temporal switching of both detectors, which are assumed to follow inertial trajectories. We identify two main cases of interest for a quantum control: space-like regions in superposition of different times, and time-like regions in superposition of different causal orders (ICO). We find in both cases that, thanks to quantum interference effects, the two detectors can gain information about field correlations that is impossible to access with only a single use of each detector in the standard scheme

with no coherent control. This is shown to have relevant consequences for information theoretic quantities, like entanglement and mutual information harvested by the detectors from the field.

Quantum Control of two UDW Detectors.— The Hamiltonian of an UDW detector coupled to a real scalar field — a simplified version of the electric dipole light-matter interaction — is given in full generality by

$$H_I(t) = \lambda_D \int d\mathbf{x} S(\mathbf{x}) \chi_D(t) (e^{i\Omega_D t} \sigma_+ + e^{-i\Omega_D t} \sigma_-) \otimes \phi(x_D(t)), \quad (1)$$

where Ω_D is the energy-gap of the detector, λ_D its coupling constant, $S(\mathbf{x})$ is a smearing function that models the spatial extent of the detector, and $\chi_D(t)$ is a window function that determines the spacetime activation regions, i.e. when the detector is on or off [55]. The $\sigma_{\pm}$ are the ladder operators of the two-level UDW detector and ϕ is the scalar field. Here and in the following we consider stationary detectors, so that $x_D(t) = x_D = \text{const.}$

We consider a composite system formed by two point-like UDW detectors, locally coupled to a real scalar field, whose Hamiltonian is

$$H_I(t) = \sum_{D=A,B} \sum_{i=0,1} \lambda_D \chi_{D,i}(t) (e^{i\Omega_D t} \sigma_+ + e^{-i\Omega_D t} \sigma_-) \otimes \phi(x_D(t)) \otimes |i\rangle_C \langle i| \quad (2)$$

where $i = 0, 1$ is determined by the computational basis states $\{|0\rangle, |1\rangle\}$ of a control qubit (system C henceforward) that governs the window functions of the detectors A and B . Placing the initial state of the qubit in a coherent superposition of the computational basis states will thus give rise to a superposition of different switching times of the two detectors.

We shall focus on two scenarios, depicted in Fig. 1, which allow us to probe two distinct physical situations. Without loss of generality in all cases considered we assume a fixed but arbitrary foliation of flat spacetime into space-like slices (hypersurfaces), each associated with a different time coordinate. Furthermore, in all scenarios each detector is switched on exactly once. In the first scenario (i) detectors A and B are switched on jointly on a common space-like slice, but in a quantum-controlled superposition of two slices associated with different times. We call this scenario a *past-future* (PF) superposition. The terms ‘past’ and ‘future’ refer to the relation between the superposed switching times. This case allows us to probe how entanglement between space-like regions of the field is affected by quantum delocalisation of these regions in time. In the second scenario (ii) detector A is switched on on the past slice and B on the future slice, in superposition with A and B interchanged. We call this scenario a *cause-effect* (CE) superposition, since for time-like separation between the involved regions the relation between A and B is causally indefinite – we have a

superposition of A in the past causal cone of B and vice versa. Importantly, even for space-like separation between A and B the CE scenario is not equivalent to the PF scenario, which justifies making a general distinction between (i) and (ii) – see Supplementary Materials [31] for further discussion.

FIG. 1: Left: scenario (i) in which the two detectors are in a superposition of being active either both in the past or both in the future, controlled by the state of the control qubit $|0\rangle$ or $|1\rangle$ respectively. In this case the spacetime activation regions for the two detectors are spacelike in both branches of the quantum superposition. Right: scenario (ii) with indefinite causal order. In this case the two detectors are active when timelike related. The quantum superposition between “ A before B ” and “ B before A ” is controlled by the state of the control qubit $|0\rangle$ or $|1\rangle$ respectively. Note that in the main text, scenario (ii) also encompasses the case of space-like separated detectors where A and B are placed at different slices of constant time. (Colours online).

We begin by determining the density matrix of the tripartite system ABC by tracing out the field degree of freedom. The evolution of the entire system is described by a unitary map that can be expanded in a Dyson series to second order in the coupling constant as $U = \mathbb{I} + U^{(1)} + U^{(2)} + \mathcal{O}(\lambda^3)$. More explicitly,

$$U = \mathbb{I} - i \int_{-\infty}^{\infty} dt H_I(t) - \int_{-\infty}^{\infty} dt \int_{-\infty}^t dt' H_I(t) H_I(t') + \mathcal{O}(\lambda^3), \quad (3)$$

where $\mathcal{O}(\lambda^2)$ terms include terms λ_A^2 , λ_B^2 , and $\lambda_A \lambda_B$. While here we employ a perturbative approach, it should be noted that some of the results in the following can be reached also with non-perturbative methods (cf. [31]).

The initial state of ABC and the field is chosen to be

$$\rho_0 = |0\rangle_A \langle 0| \otimes |0\rangle_B \langle 0| \otimes |+\rangle_C \langle +| \otimes |0\rangle_F \langle 0|, \quad (4)$$

i.e., both detectors are in their ground states, the control qubit is in a coherent superposition of computational ba-

sis states, where $|\pm\rangle = (|0\rangle \pm |1\rangle)/\sqrt{2}$, and the field is in the vacuum state. This choice of initial state greatly simplifies the computations, without concealing the physics of the problem, and it is instrumental to the study of the entanglement harvesting.

The state after a time τ such that $\max[\text{Supp}(\chi_i^D(t))] < \tau \forall i = \{0, 1\}$, $D = \{A, B\}$, is given by

$$\begin{aligned} \rho_f = U \rho_0 U^\dagger = & \rho_0 + U^{(1)} \rho_0 + \rho_0 U^{(1)\dagger} + U^{(1)} \rho_0 U^{(1)\dagger} \\ & + \rho_0 U^{(2)\dagger} + U^{(2)} \rho_0 + \mathcal{O}(\lambda^3) \end{aligned} \quad (5)$$

By tracing out the field, the reduced density matrix for the qubits ABC — to second order in the coupling constants — can be obtained as

$$\begin{aligned} \rho_{ABC} &= \text{Tr}_F[\rho_f] \\ &= \text{Tr}_F[\rho_0 + U^{(1)} \rho_0 U^{(1)\dagger} + \rho_0 U^{(2)\dagger} + U^{(2)} \rho_0] + \mathcal{O}(\lambda^4) \\ &= \frac{1}{2} \sum_{ij} \begin{bmatrix} 1 + Y_{ii} + Y_{jj}^* & 0 & 0 & \mathcal{M}_{jj}^* \\ 0 & P_{B,ij} & \mathcal{L}_{AB,ji}^* & 0 \\ 0 & \mathcal{L}_{AB,ij} & P_{A,ij} & 0 \\ \mathcal{M}_{ii} & 0 & 0 & 0 \end{bmatrix} \otimes |i\rangle_C \langle j|, \end{aligned} \quad (6)$$

whose different elements are explicitly given in [31].

The terms $P_{D,ij}$ contain two-point function field correlations between the same spacetime point/region (corresponding to the position and time at which detector D is active) if $i = j$; and two-point correlations between past and future activation regions of the same detector if $i \neq j$. The terms $P_{D,ii}$ are referred to as *local* terms since they involve the “self” correlations between the local spacetime-region of activation of a single detector, whereas the terms $P_{D,i \neq j}$, though referring to a single detector, are non-local since they contain correlations between different spacetime regions. The terms Y_{ii} are similar in nature to the terms $P_{D,ii}$ and are related to them via $Y_{ii} + Y_{ii}^* = -(P_{A,ii} + P_{B,ii})$. The term $\mathcal{M}$ quantifies the non-local field correlations between different detectors and is responsible for the harvested entanglement from the field to the detectors. The terms $\mathcal{L}_{AB}$ are the leading order contributions to classical correlations between the detectors [32] and are the only terms that contribute to the mutual information between them.

The state of the control qubit (C) governs the choice of scenario. Consider first scenario (i) illustrated in the left panel in Fig. 1. We see that $\text{Supp}(\chi_{A,i}) = \text{Supp}(\chi_{B,i})$ for $i = 0, 1$. Contrast this with the right panel of Fig. 1 depicting scenario (ii), where now $\text{Supp}(\chi_{A,i}) = \text{Supp}(\chi_{B,j})$ for $i \neq j$. We eliminate the control qubit by either tracing it out or measuring it in the basis $\{|+\rangle, |-\rangle\}$. Our notation applies to both scenario by just a different labelling of the window functions.

Tracing out the control qubit yields

$$\rho_{AB}^{(\text{tr})} = \begin{bmatrix} 1 - (P_A^{(\text{tr})} + P_B^{(\text{tr})}) & 0 & 0 & \mathcal{M}^* \\ 0 & P_B^{(\text{tr})} & \mathcal{L}_{AB}^{(\text{tr})*} & 0 \\ 0 & \mathcal{L}_{AB}^{(\text{tr})} & P_A^{(\text{tr})} & 0 \\ \mathcal{M} & 0 & 0 & 0 \end{bmatrix}, \quad (7)$$

where

$$P_D^{(\text{tr})} = \frac{1}{2}(P_{D,00} + P_{D,11}) \quad (8)$$

$$\mathcal{L}_{AB}^{(\text{tr})} = \frac{1}{2}(\mathcal{L}_{AB,00} + \mathcal{L}_{AB,11}) \quad (9)$$

$$\mathcal{M} = \frac{1}{2}(\mathcal{M}_{00} + \mathcal{M}_{11}). \quad (10)$$

The results is a classical (probabilistic) mixture of *two detectors active only once*, either spacelike related (i), or timelike related (ii), since the reduced state in Eq. (7) is the mixture (with equal weights) of the classical case in which both detectors are active only once. This should have been expected. Indeed, borrowing some intuition from the process matrix formalism [4], the situation is similar to the *quantum switch* in which an indefinite causal order is present only if the control qubit is allowed to quantum interfere [3, 14–16]. Tracing out the control qubit corresponds to losing the coherence of the superposition, effectively yielding ‘which-when’ information about detector activation and thus remaining with a classical mixture.

Conversely, measuring the control qubit in the $\{|+\rangle, |-\rangle\}$ basis and retaining, e.g., the $|+\rangle$ results, allows the control qubit to interfere, yielding

$$\rho_{AB}^{(+)} = \begin{bmatrix} 1 - (P_A^{(+)} + P_B^{(+)}) & 0 & 0 & \mathcal{M}^* \\ 0 & P_B^{(+)} & \mathcal{L}_{AB}^{(+)*} & 0 \\ 0 & \mathcal{L}_{AB}^{(+)} & P_A^{(+)} & 0 \\ \mathcal{M} & 0 & 0 & 0 \end{bmatrix} \quad (11)$$

where now

$$P_D^{(+)} = \frac{1}{4}(P_{D,00} + P_{D,01} + P_{D,10} + P_{D,11}) \quad (12)$$

$$\mathcal{L}_{AB}^{(+)} = \frac{1}{4}(\mathcal{L}_{AB,00} + \mathcal{L}_{AB,11} + \mathcal{L}_{AB,01} + \mathcal{L}_{AB,10}). \quad (13)$$

We see that, while the $\mathcal{M}$ terms are the same whether we trace out the control qubit or let it interfere, the other terms in the density matrix differ in the two cases. In particular, in $\rho_{AB}^{(+)}$ there appear terms $P_{D,i \neq j}$ and $\mathcal{L}_{AB,01(10)}$ that contain two-point correlation functions of the field between two different spacetime regions in which the same detector or both the detectors are activated in superposition. These quantum interference terms are signatory of the coherence of the superposition. It should be noted that, without the controlled superposition the field correlations contained in the interference terms would not be accessible with a single use of each detector. By placing the detectors in quantum temporal superposition, we

read out correlations between space time regions which can be accessed in the standard schemes with no superposition only if the detectors are used more than once (in more than one space-time region).

This is our primary result: quantum controlled temporal superpositions allow UDW detectors to access field correlations between spacetime regions pertaining to the two different branches in a quantum superposition. As we show in the following, this has relevant consequences for information-theoretic quantities, such as the extractable entanglement from the quantum vacuum.

Entanglement Harvesting – Let us now look at instances in which the additional correlations in (11), stemming from the quantum interference, have relevant effects.

We consider the process of entanglement harvesting from the quantum field vacuum, which is well-understood in flat spacetime [30, 33]. Entanglement harvesting has attracted much interest for its foundational and applicative relevance [30, 33–40], with possible implications for the black hole information paradox and quantum gravity [32, 41–47].

Entanglement can be harvested from the quantum vacuum, in general, even for detectors that are spacelike separated [27, 48]. However, the procedure is subject to some strict limitations [42, 49, 50]. In particular, a no-go theorem has been proven [42, 49] that states *UDW detectors with Dirac-delta window functions, but arbitrary spatial profile and coupling strength, cannot harvest entanglement*.

Remarkably this no-go theorem is violated for quantum controlled temporal superposition of UDW detectors. To prove this statement, we use as an entanglement measure the concurrence which, for identical detectors, is given by [51]

$$\mathcal{C}^{(+/\text{tr})} = 2 \max \left\{ 0, |\mathcal{M}| - \mathcal{P}_{AB}^{(+/\text{tr})} \right\} \quad (14)$$

in terms of the reduced density matrix elements in Eq. (11), where $\mathcal{P}_{AB}^{(+/\text{tr})} \equiv \sqrt{P_A^{(+/\text{tr})} P_B^{(+/\text{tr})}}$; if the detectors are identical we write this as $\mathcal{P}_D^{(+/\text{tr})}$. It is straightforward to show [52] that $\mathcal{C}^{(\text{tr})} = 0$ since $|\mathcal{M}| \leq \mathcal{P}_{AB}^{(\text{tr})}$ – this is the no-go theorem. However $P_D^{(+)} \leq P_D^{(\text{tr})}$ in general, and so $\mathcal{C}^{(+)}$ does not always vanish. We illustrate this in Fig. 2, where we see that violations of the no-go theorem can be proven both perturbatively (left, using a compact spatial profile for each detector) and non-perturbatively (centre and right, using Gaussian spatial profiles). These violations are due to the quantum interference terms that contain the field correlations between the past and future activation regions of each detector. These correlations have the effect of lowering what can be interpreted as the detector excitation probability (the P terms) with respect to a classical mixture (7). This

in turn means that local noise effects are reduced by the quantum interference terms in such a way that entanglement harvesting is not precluded.

Another instance in which effects of quantum controlled superposition are manifest is in entanglement harvesting with pointlike detectors. In this case, in order to avoid divergences, the window function needs to be something other than a delta-function [42]. In Fig. 3, we employ a compact support window function, chosen to be $\cos(2t/\eta)$ for $-\pi/4 \leq t/\eta \leq \pi/4$ and 0 otherwise, η being the “width” of such function. We see that the quantum controlled superposition allows for spacelike entanglement harvesting whereas a classical mixture does not. Moreover, it is clear that whenever the two detectors are time-like related, ICO enhances the entanglement harvesting. This is a striking demonstration of how quantum temporal interference effects can affect the ability of UDW detectors to harvest entanglement.

Discussion – Indefinite casual order, or more generally, a quantum controlled superposition of detector activation times, affect the entanglement harvesting capabilities of UDW detectors locally coupled to quantum fields. This happens under a variety of scenarios, producing the striking result that spacelike entanglement harvesting becomes possible in situations not possible for classical mixtures. Note that the additional entanglement does not come directly from the control qubit. If there were no field (i.e. $\phi \rightarrow \mathbb{I}$) in Eq. (2), then after the interaction, the detectors would remain separable.

While we have focused on entanglement harvesting as a relevant example, it should be noted that the quantum interference terms affect also the total amount of correlations that the detectors can harvest. This is quantified by their mutual information (cf. [31]) in which the term $\mathcal{L}_{AB}^{(+)}$ appears, which does not play any role in the entanglement harvesting, and which encodes field correlations between activation regions of the two detectors pertaining to separate quantum amplitudes of the process.

It is crucial to note that, the same field correlations entering Eq. (12) would also be present if both detectors were active at two distinct times (and in the same space-time regions as for the quantum superposition case), a scenario we call ‘double switching’. In fact, for double switching violations of the no-go theorem are trivially possible, since the theorem requires each detector being active only once [50]. However, the reduced state of AB would differ from $\rho_{AB}^{(+)}$. Perturbatively, the difference would be in the $\mathcal{M}$ terms, meaning that the entanglement harvesting would be significantly different (while the mutual information would be the same). Quantum temporal superposition is therefore in principle distinguishable from the case in which each detector is twice activated (at least in certain parameter ranges, cf. [31]), allowing for a clear way to unambiguously state that the

FIG. 2: Left: perturbative violation of the no-go theorem in 2+1 dimension for detectors with spatial compact support and Dirac-delta window function. The spacetime configuration of the two detectors — corresponding to a PF scenario with detectors A, B active at times t_i^A and t_i^B with $i = 0, 1$ determined by the control qubit — is shown on the lower-right. The disks of radius σ represent the spatial compact support. The violation happens whenever $|\mathcal{M}| - \mathcal{P}_D^{(+)} > 0$. We plot this quantity as a function of spatial separation s and temporal separation T between activations in the different branches of the superposition. No violation occurs if $\mathcal{P}_D^{(+)}$ is replaced with $\mathcal{P}_D^{(\text{tr})}$. Values used for the parameters are $\Omega = 3$, $\sigma = 1$, $\delta = 10^{-5}$. Note that, when $T < s - 2\sigma - \delta \wedge s > 2\sigma \wedge \delta < s - 2\sigma$ the activation regions of detector one are spacelike related with the ones of detector two. In the figure, this situation corresponds to the lower triangular area of the plot. Centre: non-perturbative violation of the no-go theorem for Gaussian spatial profiles in 3+1 dimensions with CE superposition. Right: non-perturbative violation of the no-go theorem for Gaussian spatial profiles in 3+1 dimensions with PF superposition. In the centre and right panels black dots represent the regions where no entanglement can be harvested. The detectors have a window function $\chi(t) = \eta\delta(t - t_i^D)$, a smearing function of $S(\mathbf{x}) = \frac{\exp[-(\mathbf{x}/9)^2]}{(9\sqrt{\pi})^3}$, an energy gap of $\Omega\eta = 1$ and couple to the field with a strength of $\lambda = 1$. The elements of the reduced density matrix have been numerically calculated to 15 significant figures. (Colors online).

FIG. 3: The concurrence of the perturbative reduced density matrix of two point-like detectors that couple to the field with a cosine window function in a (left) quantum controlled CE superposition and (right) a classical mixture of A before B and B before A plotted as a function of the spatial separation, s and the temporal separation T of the detectors. The green lines mark the region of spacelike separation of the detectors and the black dots represent the regions where no entanglement can be harvested. For the chosen parameters, spacelike entanglement harvesting is possible only when the detectors are in the CE superposition. The energy gap of the detectors is $\Omega\eta = 3$. The elements of the reduced density matrix have been numerically calculated to 15 significant figures. (Colors online).

detectors in the superposition are activated only once.

In light of this discussion, our results imply that UDW detectors with compact spacetime support qualify as good candidates for *local laboratories* in the process ma-

trices framework [4]. In this respect, it would be interesting to analyse coherent superpositions of detectors from the point of view of the process matrices formalism as a first step toward generalizing the formalism from quantum mechanics to quantum field theory.

Finally, while correlations harvesting serves as just an instance of a more general framework, it well exemplifies the potential of probing a quantum field — and thus spacetime itself [53], to some extent — with quantum coherent superpositions of locally coupled detectors. This opens up to the possibility to use coherent superpositions of detectors as efficient probes of quantum fields.
