- Century-long changes in the distribution and phenology of arctic mountain plants 1 2 Andrew S. MacDougall^{1,2,#}, Paul Caplat³, Johan Olofsson², Matthias B. Siewert², Colin 3 Bonner¹, Ellen Esch¹, Malie Lessard-Therrien¹, Hannah Rosenzweig², Anne-Kathrin 4 Schäfer², Hassan Ridha², Kjell Bolmgren², Thore C.E. Fries^{*}, Keith Larson,^{2,#} 5 6 7 ¹Department of Integrative Biology, University of Guelph, Guelph, Ontario, Canada; ²Climate 8 Impacts Research Centre, Umeå University, Umeå, Sweden; ³School of Biological Sciences, Queen's University, Belfast, Northern Ireland; *[Abisko Natural Science Station (1886-1930)] 9 *#corresponding authors* 10 11 Abstract: Arctic species are well adapted to climatic variability, but their long-term responses to 12 warming remain unclear. Responses may be across-generation, via migration, or within-13 generation, involving phenological shifts in the timing of growth and reproduction. Using 14 unprecedented century-long (1917-1919 vs 2017-2018) data on migration and phenology for 83 15 arctic and boreal mountain species in northern Sweden, we show dramatic distributional change 16 17 associated with warming. 69% of species shifted uphill, averaging 6.1 m per decade, especially boreal woodland taxa whose upward expansion reduced unforested arctic habitat by 30%. 18 Simultaneously, 20% of summit species were displaced downslope especially moisture-19 20 associated snowbed flora. Comparing differences in emergence, senescence, and duration of leafing and flowering between the early 1900s and present-day, we detected wide interannual 21 variability in leafing and flowering within the two eras but no detectable shift between them. 22 23 This was explained by two mechanisms. First, plant emergence mirrored snowmelt, whose timing was influenced by warmer years having greater snowfall – warmer springs did not always 24 result it earlier emergence because snowpacks persisted longer. Second, the onset of reproductive 25 26 senescence was unchanged even between years when emergence differed by a month – species that started earlier finished earlier, possibly due to intensified summer heat stress or canalized 27 "hard-wiring" where the timing of senescence occurs regardless of summer temperature. 28 29 Migrations in this system have likely buffered species loss. However, boreal expansion, warming 30 temperatures, altered snow accumulation, and a potential lack of flexibility in timing of senescence may foreshadow challenges for high-latitude flora. 31 32 33 Keywords: arctic flora, climate change, resiliency, migration, phenology, mountain, historical 34 data. 35 36 Introduction 37 The Arctic climate is one of the more rapidly changing on the planet, having warmed by 2-
- 3°C over the last century with projected increases towards 4°C (Nogues-Bravo et al., 2007, 38
- 39 Parmesan & Yohe, 2003, Sala et al., 2000). These changes have significant consequences for
- arctic flora, including on mountains where warming can be especially pronounced (Lenoir et al., 40
- 2008, Prevey et al., 2019, Steinbauer et al., 2018), growing seasons short, and the availability of 41 high-elevation refugia finite (Prevey et al., 2019, Steinbauer et al., 2018).
- 42
- 43 The biological impacts of a changing arctic climate, on mountain plants and more broadly, will be dictated by their ability to maintain growth and reproduction. This occurs by two 44
- 45 pathways: migration across generations, progressively moving northward, uphill, or both, and
- phenological adjustments that better match growth and reproduction to changes including 46

warmer springs, drier summers, extended periods of autumn warmth, and altered precipitation 47 dynamics including snowfall (e.g., Alexander et al., 2015). However, the capacity for resilience 48 emerging from these mechanisms, historically and going forward, remains unclear. Persistence 49 50 of high-latitude plants is strongly dictated by distributional range and phenology, given the compressed growing season of the arctic climate (Harsch et al., 2009). There are numerous traits 51 that could well-equip Arctic species for rapid phenological adjustments to warming, such as 52 early emergence, delayed reproduction, or extended leafing senescence. These same traits could 53 54 also predict species loss, if climatic change exceeds the trait-based limits of adjustment, or if change favors suites of larger- and faster-growing competitively superior southern invaders 55 (Alexander et al., 2015). If high-latitude plants cannot phenologically adjust, then multi-56 57 generational upward or northward shifts via migration will be needed to maintain the climatic envelope, escape southern invaders, or both (Alexander et al., 2015). 58

59 It has been difficult to empirically determine whether plants are successfully adjusting to a changing Arctic climate, given an absence of long-term data especially prior to recent decades 60 when warming has accelerated (Steinbauer et al., 2018). There is some evidence for both spatial 61 and phenological shifts (Lenoir et al., 2008), but there has also been wide variability in response 62 (Myers-Smith et al., 2015). For example, sometimes shrub- and tree-lines advance in elevation 63 or latitude but many times they do not (Harsch et al., 2009, Myers-Smith et al., 2015, Van 64 Bogaert et al., 2011). The same holds for changes in species richness of cold-adapted plants – 65 66 there has been reports of increases (Klanderud & Birks, 2003), losses (Engler et al., 2011, Wilson & Nilsson, 2009), and no change (Vanneste *et al.*, 2017). Furthermore, research tends to 67 target the front of the range (expansion), whereas range changes may derive more from the back 68 (contraction) especially if climate impacts are indirectly channeled through altered species 69 interactions (Van Bogaert et al., 2011). In this latter case, phenological changes alone will not 70 buffer warming if "warm-tolerant" species are sweeping in from behind - only northward or 71 72 upward range expansion by arctic flora would maintain persistence. Phenologically, there has been an understandable emphasis on early flowering given the advancement of growing seasons 73 globally (Alexander et al., 2015), but growing season length and senescence also impact plant 74 fitness and are less investigated in the arctic (Prevey et al., 2019). Even so-called "Arctic 75 greening-up" in high-latitude plant communities, involving extended growing seasons and 76 increased net primary production, has not been universally detected (Myers-Smith et al., 2011, 77 Pauchard et al., 2016). In total, these uncertainties on phenological and migrational responses 78 79 limit our ability to predict future impacts of a warming Arctic (Niskanen et al., 2019) Here, we present evidence of century-long distributional and phenological adjustments by 80 83 arctic and boreal mountain flora in northern Scandinavia. Climate conditions in this region 81 have changed dramatically especially since the 1980s (Fig. S1), while the arctic mountain plants 82 of northern Scandinavia have been modelled to undergo substantial species loss and range 83 contraction (Niskanen et al., 2019). Our work centers on a unique 100-year dataset, identically 84 85 sampled in 1917-1919 and in 2017-2018 along an elevational gradient straddling both Arctic and Boreal biomes in the Scandes Mountains. Using data on shifts in the onset and senescence of 86 leafing and flowering, changes in elevational occurrence, the timing of snow melt, along with 87

species-specific plant traits and local daily climate data back to 1914, we test the relative

importance of migration and phenology on plant persistence. Our distributional analysis includes
 data on the maximum and minimum range limits of each species, allowing us to determine if

91 change happens more at higher elevation, where direct temperature effects should be most

92 limiting, or towards the mountain base where climate impacts should be channeled through

93 species interactions especially invasion by southern taxa. We also test differences in the richness

and composition of summit vegetation, given that mountain tops can be especially sensitive to

95 climate change as described elsewhere in Europe (e.g., Pauli et al. 2012; Gottfried et al. 2012;

96 Matteodo et al. 2013).

97 Methods

98 Work was conducted in two sampling periods on a 900 m ASL long elevation transect on Mount Nuolja (1169 m ASL) in Abisko National Park, Sweden, located 195 km north of the 99 arctic circle (68.3495° N, 18.8312° E). The study area occurs within a rain shadow of the 100 Scandes Mountains, with long-term (1914-2013) precipitation averaging 307 mm per year and 101 mean annual temperatures of -0.5° C. About 50% of annual precipitation falls as snow typically 102 103 between October-April. Snowbeds can persist well into the summer months, depending on elevation, and in some years there are areas that maintain snowcover for the entire summer. All 104 climate data come from a meteorological station at Abisko Scientific Research Station (founded 105 1913), near the base of the transect (388 m ASL) – data were measured every three hours from 106 1914-2004, and then hourly since (Kohler et al. 2006, Callaghan et al. 2010). Long-term 107 trajectories of warming over the 20th and early 21st centuries at the station show increases, but 108 109 these trends are not linear. The most consistent period of increased warming has been since the 1980s (Fig.S1), with the largest relative changes involving warmer spring and fall seasons. Prior 110 to the 1980s, inter-decadal warming was more variable including extended cold winters during 111 112 the 1950s-70s.

The Abisko region straddles the boreal and arctic vegetation zones of northern Scandinavia. 113 Boreal areas of Abisko are currently dominated by the subalpine mountain birch (Betula 114 pubescens), with some pine (Pinus sylvestrus). Unforested tundra alpine areas are most often 115 confined to upper mountainous slopes, including Mt. Nuolja (Fig. S2A), with a high diversity of 116 dwarf shrub and herbaceous plants. The region has been widely grazed by domesticated reindeer 117 for centuries with varying intensities and land use practices since the 1800s (Emanuelsson 1987). 118 Major predators have largely been eliminated. Our study site on Mt. Nuolja lacks melting glacial 119 beds and has some of lowest levels of anthropogenic-based nitrogen deposition in Europe 120 (Dentener, 2006) - both can otherwise accelerate uphill colonization of plants, confounding tests 121 of direct climate responses. 122

The study transect consists of twenty permanent monitoring plots established from base to 123 summit in 1916 (Fig. S2). All work during 1917-1919 was conducted in 78 subplots within the 124 125 20 plots, with data amalgamated to the plot level for analysis (Fries 1925). These subplot data were subsequently lost, thus all historical comparisons in this paper are among-plot. The plots 126 are separated by an average of 18.6 m of elevation depending on the steepness of the mountain 127 face (range 8.9 - 63.06 m). The longest annual duration of sampling during the first survey 128 period was 1918, from May 25th-August 31st. Sampling ended earlier in 1917 (August 7th) and 129 1919 (June 24th). 130

131 Initial sampling from 1917-1919 involved monitoring of plant phenology, including onset and senescence of leafing and flowering, for all species at five-day intervals starting May 25 of 132 each year when most plots tended to be snow covered. The repeated visitation of plots helped 133 134 accurately identify all species, with sufficient frequency to capture the timing of phenophase 135 transition. The frequency of plot re-visitation, however, demanded logistical trade-offs given the mountainous and often snow-covered terrain with many dozens of species. To that end, all 136 137 phenological data were assessed at the plot level, thus ignoring the abundance and phenological variation of each species within each plot. For example, the timing of leaf senescence for a 138

species would be determined by the first observation of senescence by any individual of that
species in that plot. If that species was found in ten plots on the transect, then there would be ten
datapoints for that species at each sampling period.

In addition to phenological shifts, the percent coverage of snow per plot was also repeatedly measured every five days - this was conducted given the importance for the timing of snowmelt by elevation for arctic plant phenology (e.g., Wookey et al. 2009, Semenchuk et al. 2016). A 50 m measuring chain was sequentially laid, plot by plot, along the entire mountain transect, with % snow cover determined by the distance of the chain contacting snow versus open ground. This procedure was used 1917-1919 and again in 2017, before switching to a

148 Trimble R8 dGPS (2018-present).

The transect plot markers were periodically maintained as recently as the 1960s, enabling 149 relocation of 59 of the 78 subplot poles along the transect in 2016. Areas without poles were easy 150 to identify given the detailed description of distance and bearing between the poles (Fries 1925), 151 and because the piles of rocks used to support the missing poles often remained evident. We 152 were thus able to conduct our contemporary surveys in the exact locations of the 1917-1919 153 work, with one exception. In 1964 a chairlift was installed that bisected the gradient within the 154 155 birch woodland at ~650 m ASL; three of the poles were shifted by ~10 meters in the summer of 1964, perpendicular to the axis of the gradient. 156

During 2017 and 2018, the survey protocols for phenology and snow cover as described for 157 158 1917-1919 were followed identically. By using the exact plot locations, we were able to detect the altered plot-level distribution and performance of each species. For migration, we were able 159 to determine changes in mean plot distribution, shifts in the upper maximum plot occurrence, 160 changes in the lower minimum of occurrence, and whether species ranges have expanded or 161 contracted from the top, the bottom, or both. To calculate spatial shifts, we used plant data from 162 1918 as it had the widest span of observations from May 25th- August 31st. The 2017 and 2018 163 data included this May 25th - August 31st interval. 164

For phenological change, we pooled 55,016 observations from 83 vascular plant species deriving from the repeated species-specific plot visitation every five days from the two eras. The data from 1917-1919 contained 156 species (Fries 1925), representing 47% of all species known from Abisko National Park at the time (Fries 1910). We recorded an additional 15 species during our sampling period, while observing all of the previously reported species on the transect or nearby on the mountain. Our 83 species were selected based on being present in both eras and occurring in three of more plots. We eliminated several morphological cryptic taxa as a

172 precautionary measure because of uncertainty about their historical distribution (e.g.,

173 *Anthoxanthum odoratum* vs *A. alpinum*, some sedges and willows). Overall, there was a wide

174 range in plot frequency per species (n/20 plots), with occupancy among the 83 species averaging

40%. Three species occurred in a maximum of 15/20 plots, while 1.5% of the species were only

found in one plot in one or both sampling periods.

We classified the 83 species into four habitat categories, to test whether species responses unfolded in definable 'syndromes' based on established affinities with temperature and soil

179 moisture (Table S1). Boreal flora derive from forested habitats with southerly distribution

180 centers - these taxa tend be expanding rapidly into the warming Arctic (Vuorinen et al. 2017;

181 Bjorkman et al. 2018). Soil moisture classifications centered on taxa with "broad" tolerances

182 including xeric conditions, and cold-affiliated "mesic" species that are typically associated with

moist soils derived from seeps and melting snowbeds. We also determined major traits of leaf

biomass, leaf surface area, and plant height for each species, testing whether plant morphology

predicted migrational response over time. Data were combined from the TRY and the Tundra
Trait Team databases (Kattke et al.2011; Bjorkman et al. 2018).

All phenology stages were defined by Fries (1925). The phenology classification for each 187 species was summarized at the plot level, for six response variables: first observed onset of 188 leafing species⁻¹ plot⁻¹, first observation of leaf senescence species⁻¹ plot⁻¹, first observed onset of 189 flowering species⁻¹ plot⁻¹, first observation of flower senescence species⁻¹ plot⁻¹, and the duration 190 of leafing and flowering based on the differences between onset and senescence for each species. 191 Senescence was defined as detectable changes in leaf or flower colour, or the onset of visible 192 wilting. For each of the six responses, we calculated log response ratios derived from differences 193 in means among plots for the two sampling periods. 194

Changes in elevational occurrence were calculated by comparing differences in plot 195 presence/absence between the two sampling periods. As described, we lacked exact measures of 196 where individual plants occurred within a plot, but we did know the elevations of the plots they 197 occupied. We thus calculated change based on those plot elevations. For example, a species 198 occurring in plots 1-3 in 1918 would have a mean elevation of 437.02 m based on the three 199 starting elevations of the plots (418.2, 436.3 m, and 456.6 m). If that same species was found in 200 201 plot 8-10 in 2017, then its current mean elevation would be 705.5 m and its change over time would be an increase of 287 m (or 28.7 m per decade). We calculated elevational shifts in the 202 maximum and minimum plots of occurrence, simply by taking the differences of these two 203 204 measures between the time periods.

We used aerial drone imagery to test relationships among estimated plant productivity 205 (NDVI), elevation, and species distribution, given that standing biomass can represent plant-206 plant competitive dynamics especially at lower elevations including impacts on ground level 207 temperatures, light, and the timing of snowmelt (i.e., Alexander et al. 2017). Aerial imagery was 208 collected between 23-27 June 2018 using an eBee fixed-wing drone (senseFly, Switzerland) in 209 combination with a Sequoia multi-spectral sensor (Parrot, France) and a SONY DSC-WX220 210 RGB camera. NDVI was calculated from the multi-spectral sensor and radiometrically calibrated 211 using Mosaic Mill reflectance targets. The imagery was georeferenced to >10 known DGPS 212 locations of equally distributed poles along the transect visible in the imagery. Pix4dmapper was 213 used for post-processing of the imagery (Pix4D, Switzerland). A 2 m resolution digital elevation 214 model (© Lantmäteriet, Sweden) was used to derive terrain variables in SAGA GIS (44). These 215 include slope, wind exposition index, SAGA wetness index and annual potential incoming solar 216 217 radiation. NDVI and terrain variables were extracted on a per pixel basis along a 10 m wide buffered band along the 20 plots and are summarized in Table S3. 218

Our primary analyses centered on describing the magnitude and direction of elevational 219 and phenological changes among the 83 species, using log proportional change in means (log 220 response-ratios) between the two study periods. We used principle components analysis to 221 examine relationships between major plant traits and the extent of mean, maximum, and 222 223 minimum elevational change for the four major habitat groupings of plants. We used linear regression to test relationships between elevation and snow melt by year and season; how 224 elevation influenced the timing of the onset, duration, and senescence of leafing and flowering; 225 226 and to determine associations between species-specific distributional changes at the maximum 227 and minimum elevations of occurrence. We used multiple correspondence analysis (MCA) to test associations between four vegetation classes based on temperature and moisture, and 228 229 whether species were lost, gained, or remain unchanged. All analyses were conducted on JMP 230 14.0 (SAS Institute Inc., Cary, NC, 1989-2019).

231 **Results**

The most detectable century-long changes were spatial/elevational rather than

phenological. Since 1918, 95% of the 83 species had altered mean distributions along the

montane gradient (Fig. 1). Most of these shifts have been upward, affecting 69% of all taxa.

There has been significant widening of species ranges, averaging 7.5 m per decade and mostly explained by increases in upper range limits. There were four species lost from the transect

230 explained by increases in upper range initis. There were rour species lost from the transect237 (Table S1), although each currently resides nearby (within ~1 km) on the mountain (Larson,

unpublished data) - we thus found no evidence of local extirpation despite pronounced warming

in recent decades (Fig. S1). Conversely, there were fifteen new occurrences since 1917-1919,

240 mostly larger-sized herbaceous species with Boreal affiliations (Figs. 2AB, Table S1).

241 Although many species had higher average ranges, there was no single shared response by all taxa (Fig. 1). While mean range shifts averaged 6.1 m decade⁻¹, variation among species 242 ranged 10-fold. Some species climbed $\sim \frac{1}{2}$ km over the last century while others descended to the 243 same extent. Further, higher mean range shifts were associated with two responses: contraction 244 from the bottom or expansion at the top (contraction: $F_{1,82} = 6.1$, p<0.02; expansion: $F_{1,82} = 21.1$, 245 p<0.0001). Few species demonstrated both responses, such that increases in upper and lower 246 247 occurrence limits were not consistently related ($F_{1,82} = 1.4$; P = 0.24). Range contraction from the base of the mountain by arctic-affiliated taxa was presumably related to an inability to persist in 248 expanding woodland and shrub thickets (Fig. 2), especially in areas formerly characterized as 249 250 open habitat but now with significantly greater standing biomass (Fig. S3C).

At the mountain summit, there were small net changes in overall species richness but high 251 turnover since 1917-1919. There were 17 new summit species, mostly boreal taxa, that coincided 252 with the loss of 20% of species formerly present (Figs. 3 and S4; Table S2). Loss from the 253 254 summit were mostly mesic arctic species of wetter and cooler vernal conditions (Fig. S4). These taxa were largely displaced to lower elevations (Fig. 1), where snowbeds persist longer (Fig. 4). 255 256 Interestingly, there was not a dramatic change in the timing of snowmelt at the summit since the early 1900s - the summit has always become snow-free earlier in the season compared to 257 downslope, presumably due to high wind exposure (Figs. 4, S2B). 258

Downslope, the treeline was higher by 63 m since 1918, subsuming the former zone of
shrubs (Fig S2A). That shrub zone, however, expanded even more and is now 123 m higher.
Overall, expansion of the forest and shrub zones has decreased the open alpine zone by ~30%
since 1918 (Fig. S2). This upward expansion of woody plants into high-elevation open areas
appears to be on-going, with juveniles of a number of forest species including birth trees found
in all plots above the shrubline including the summit (Fig. 3).

Snowmelt dynamics among the five years examined (1917-1919, 2017-2018) varied 265 strongly by elevation and by year, but not by 'era' in the sense that trends in the early 1900s and 266 267 present-day were similar (Figs. 4A, B). Our data for local long-term winter weather (defined as Nov-Mar each year) and plot-level snow melt clearly illustrate the well-established positive 268 269 connection between higher winter temperatures and increased precipitation ($F_{1.528}$ =19.47; p<0.0001). There was variation with in snowbed persistence with elevation, with middle of the 270 transect maintaining snow the longest into the summer (Fig. 4). This trend has not changed over 271 272 the last century with the lower and warmer forested areas and upper and more exposed summit becoming snow-free weeks or even months earlier (May 25th snowmelt [year, elevation]: - F_{5,119} 273 = 1.63; p = 0.157; Figs. 4, S3). 274

There was wide interannual variability in phenology, but no overall change in communitylevel phenological duration (Figs. 5AB). The net effect is a similar pattern of plant emergence

relative to snowmelt between 1918 and 2017-2018, with high interannual variability depending 277 on winter temperatures but no overall difference in snowmelt starting time on May 25th or 278 elevation over the growing season (Fig, 4). For example, winter 2017 was warmer with more 279 280 precipitation (Fig. S1), extending the spring melt period that, in turn, delayed plant emergence compared to 1918. By contrast, 2018 had a cold and dry winter with little snow (Figs. 4, S1), 281 such that many plots were snow-free in late May - predictably, emergence of leafing and 282 flowering was faster in 2018 than 1918. Phenological duration was also maintained by a tight 283 connection between emergence and senescence – species that started earlier also ended earlier, 284 for both leafing and flowering (Fig. 5). The net effect was that the duration of growing season, 285 defined as emergence to senescence, was largely unchanged between 2017 and 2018 versus 1918 286 287 $(F_{2.602} = 2.28; p = 0.104)$, even though emergence in 2018 was almost 30 days earlier on average per species compared to 2017 (Fig. 5). 288

Discussion

289

290 We tested for changes in the distribution and phenology of arctic mountain plants with an unprecedented century-wide dataset. Given pronounced local warming especially since the 291 1980s, we predicted a high likelihood of range shifts, species displacement, and the dramatic 292 293 alteration of leafing and flowering. Overall, we did observe pronounced ranges shifts by most species, accompanied by the invasion of southern-affiliated flora. Phenologically, however, there 294 were no pronounced differences between the timing and duration of emergence and growth 295 296 between the two survey periods - relationships among snow melt, the onset of leafing and 297 flowering, and the timing of senescence were similar between the two eras. We also observed no evidence of species loss – all taxa seen in the early 1900s were present in the plots or, if 298 299 displaced, still occurred nearby on the mountain. These data represent a rare opportunity to look back in time, to test for evidence of resilience mechanisms involving migration and phenological 300 timing against significant warming. They reveal that distributional shifts, including range 301 302 contraction, have likely helped to maintain the persistence, especially against the upward expansion of southern-affiliated plants. However, ongoing invasion by boreal taxa into the 303 remaining open arctic habitat, and a potential lack of flexibility in the timing of senescence 304 among many arctic plants could indicate looming challenges. 305

One limitation in quantifying past climate responses in the arctic, including resiliency, has 306 been a rarity of spatially precise long-term data. A warmed arctic can be more productive and 307 highly invaded by southern taxa yet variability in these patterns can be widespread for reasons 308 309 that are not always clear (Myers-Smith et al. 2020). These mixed responses could reflect lags created by long generation times of plants, the possibility that substantial change occurred prior 310 to onset of most studies, or that range impacts are localized thus affecting some portions of the 311 range more than others. We observed evidence suggesting the influence of each of these 312 313 confounding factors, providing critical insight on the magnitude of change for arctic plants and the underlying causal mechanisms. 314

315 Distributionally, we see an average mean range shift at 6.1 m higher in altitude per decade less than the 11 m estimate of Chen et al. (2011) but identical to Parmesan and Yohe (2003). 316 These higher mean ranges reflect upward migration, lower contraction, but rarely both. Changes 317 318 in maximum elevation have commonly been used to assess montane range shifts but can be 319 biased if they reflect rare dispersal events - our work shows that mean and maximum range shifts closely align. At the summit, we see limited change in species richness that are contrary to other 320 321 studies reporting big gains or big losses (citations), yet we also observed substantial turnover 322 especially downward shifts by mesic taxa (Crimmins et al., 2011). Finally, our species-specific

migration data illustrate a complex mixture of expansion, contraction, and retreat, demonstrating the challenges in assessing the drivers of distributional change in arctic flora. For example, the upper range limit of mesic species *Oxyria digyna* dropped by 114 m since 1917-19 but its mean elevation only changed +10 m because of a similarly large contraction from below (204 m higher) - the small change in mean distribution hides a narrowing range width by 318 m.

Despite these notable species-level changes in distribution, we still detected several broad 328 response syndromes - rapidly climbing boreal species invading from lower elevations, a small 329 group of arctic species whose mean distribution shifted downhill (14% of all species), and a 330 group of arctic species with higher mean distributions driven by contraction from below which 331 presumably reflects species interactions. Invading southern species were typical of Boreal 332 333 Scandinavia with distributional centers below the Arctic circle, including the widespread canopy tree Betula pubescens and a suite of woody shrubs especially non-Arctic species of Salix. This 334 expansion of woody trees and shrubs into Arctic landscapes is consistent with observations 335 globally (Myers-Smith et al., 2011). There was also a compliment of invading herbaceous flora 336 mostly of the forest understory, which have been reported as expanding to higher latitudes and 337 elevations elsewhere (Pauchard et al., 2016), and are generally taller and faster growing than 338 339 typically more prostrate arctic flora. Interestingly, many of these southern invaders are palatable to reindeer, with preferential grazing elsewhere acting to stabilize arctic communities against 340 their establishment (Olofsson et al., 2009). Indeed, reindeer herds persist on Mount Nuolja, 341 342 sometimes in large numbers, but do not occur at the consistently high densities seen elsewhere in the Scandes Mountains, and obviously not in high enough densities to stabilize tree and shrub 343 expansion. In particular, the use of the lower parts of the transect by reindeer have decreased 344 since the 1917-1919 due in part to changes in herding practices (Callaghan et al., 2013) – this 345 may play a contributing role in the upward invasion of plants at our site, that might be resisted 346 elsewhere (Sorensen, 1941). 347

348 The second response group was arctic flora of mesic habitats, with generally narrower and lower range occurrences. Long-term studies on climate responses by summit plants have 349 occurred across the Europe, sometimes showing large changes in species richness, by a range of 350 mechanisms (Pauli et al., 2012, Steinbauer et al., 2018). The trends with our summit taxa reveal 351 great change but also complex mechanisms, that characterize the data as a whole - things are not 352 simply warmer and less snowy. On top, no change at all in snowmelt but big turnover 353 nonetheless with the displacement of arctic-affiliated species. The bigger change, however, 354 355 maybe be the warming of Arctic temperatures, suggesting that even if the timing of snow melt may not differ substantially due to higher snowfall, plants are likely experiencing warmer and 356 possibly drier conditions when they emerge. The net effect for mesic arctic species is a 357 displacement to lower elevations where snowbeds persist longer. The ones establishing are a mix 358 of wind-dispersed species but also ones occurring with broader habitat affiliations including drier 359 sites. Importantly, this reinforces that arctic climate reflects complex temperature and moisture 360 361 interactions which will variously affect plants - warming responses will differ profoundly depending on moisture levels. 362

Finally, there was a response group of arctic species associated with areas of open meadow between the treeline and summit. This part of the transect has the longest persisting snowbeds each year, a trend that has not changed over the last century with the lower forested areas and upper summit becoming snow-free weeks or even months earlier. Overall, expansion of the forest and shrub zones has decreased the size of this open alpine zone in our plots by ~30% since 1918, consistent with other systems showing that arctic mountain species can become increasingly habitat limited as southern species sweep uphill. This suggests competition from
below is the biggest driving factor of change. Numerous studies have shown the importance of
indirect climate effects channeled through vegetation shifts. Indeed, we observed birch trees even
in summit plots, as well as everywhere else. These "invaders" were only seedlings, with the
absence of adults indicating upward dispersal but also too extreme for survival at least for the
time being. This illustrates a core challenge for arctic mountain plats being squeezed from both
sides, that may limit their ability to persist as invaders rush towards the summit.

376 Distribution shifts are a longer-term response to climate involving new colonization. Given the dramatic interannual and interdecadal swings in climate seen in our study region since 1914, 377 shifts in phenological timing would presumably be a more immediate mechanism of resilience. 378 Indeed, such shifts have been seen widely in arctic flora, including both earlier emergence and 379 contraction of flowering seasons (Prevey et al., 2019). Other studies have shown the importance 380 of warmed autumns, for extending growing seasons and invasion (Fridley), which are less tested 381 in arctic systems compared to early vernal patterns (Gallinat et al., 2015). Here, we possess an 382 unprecedented measure of plant leaf and flowering phenology. In short, we see dramatic 383 interannual variability in phenology that was similar within both eras, but no overall change 384 385 among them in terms of community-level phenological duration – unexpectedly, the length of time between emergence and sensence in the early 1900s and now were similar. 386

The reasons for this lack of overall change in duration appear to be two-fold. Foremost is 387 388 the timing of snow-melt – we found that phenological emergence each year is regulated by snow cover, not warming per se (e.g. Bjorkman *et al.*, 2015), and the average timing of snow melt 389 since 100 years ago has not shifted substantially, by elevation or timing in spring. Our data for 390 local long-term weather and plot-level snow melt clearly illustrate the well-established positive 391 connection between winter (Nov-Mar 1914-2018) temperature and precipitation: our region is 392 warmer overall, and as a result warm winters receive higher snowfall that takes longer to melt in 393 394 the spring. The net effect is a similar pattern of plant emergence relative to snowmelt between 1918 and 2017-2018, with high interannual variability depending on winter temperatures, but no 395 overall difference in snowmelt starting time on May 25th or elevation over the growing season. 396 For example, winter 2017 was warmer with more precipitation, extending the spring melt period 397 that, in turn, delayed plant emergence compared to 1918. By contrast, 2018 had a cold and dry 398 winter with little snow, such that many plots were snow-free in late May – predictably, 399 emergence of leafing and flowering was faster in 2018 than 1918. 400

The second factor preserving phenological performance was a tight connection between emergence and senescence – species that started earlier also ended earlier, for both leafing and flowering. The net effect was that the duration of growing season, defined as emergence to senescence, was largely unchanged between 2017 and 2018 versus 1918 even though emergence in 2018 was almost 30 days earlier on average per species compared to 2017. Reports of lack of change in phenological duration have been made elsewhere in the Arctic (Semenchuk *et al.*, 2016). Our work indicates this could be a consistent outcome even at a century scale.

The reasons for tight linkages of emergence and senescence are difficult to determine. One possibility relates to growing conditions in 2018, with a considerably warmer summer potentially triggering early senescence – mean temperatures in May 2018 were six times warmer than the previous year, and never went below zero. July 2018 was 3 times warmer than July 2017, with highs of 23° C. These spring and summer temperatures for 2018 are well above both centurylong and 30-year averages for our region. An alternative explanation is the presence of some level of adaptive canalization in arctic plants, where the duration of phenological periods are fixed relative to emergence even though growing conditions into the summer could remain favorable (Semenchuk *et al.*, 2016). Several arctic studies have alluded to this possibly of phenological "hard-wiring" (Sorensen, 1941, Starr *et al.*, 2000, Wookey *et al.*, 2009). The reasons for canalization could relate to evolved physiological time constraints on reproductive completion, to mitigate the risk of late-summer cold or drought sometimes characteristic of

420 Arctic summers. They may also be adaptive connections that maintain synchrony with

421 pollinators, which also emerge at snowmelt and can have short foraging seasons at high latitudes
422 (Semenchuk *et al.*, 2016). Regardless, the net effect is no detectable net change in duration

despite significant climate changes. It is critical to note that this does not necessarily mean there

424 are no adaptations to arctic warming. However, if they have occurred, they are difficult to detect 425 in the field because inter-annual changes are so vast as to mask any adaptive changes during the 426 last 100 years. As well, almost all of the 83 species were examined are longer-lived perennials

427 especially arctic plants, such that 100 years of warming may still only cover one of several
428 generations.

There are several prognoses for the future of our high-latitude mountain plant community.
One, ongoing upward expansion from southern species threatens to increasingly restrict the
extent of non-forested habitat, as has been observed repeatedly elsewhere (e.g., Arft *et al.*, 1999,

Van Bogaert *et al.*, 2011). Indeed, we recorded the presence of one or more juveniles of Boreal species in every plot above the shrub line, with *Betula pubescens* seedlings even recruiting on the summit. These individuals may not survive, but demonstrate persistent establishment at higher elevations with ever-warming conditions presumably increasing survival odds (Kullman, 2002)

and a very real risk of treeless alpine disappearing altogether (Moen *et al.*, 2004).

Secondly, we detected migration shifts by most species since 1918, which we interpret 437 primarily as direct or indirect responses to warming. Clearly arctic montane plants face 438 challenges in time and space. Temporally, the easiest responses are immediate within-season 439 440 adjustment in phenology to snowmelt and summer temperatures, which we noted for most species (Fig. 4). Given the wide range in timing of emergence in 2017 (late) vs 2018 (early), 441 most arctic species appear capable of making these adjustments. Spatially, however, the risk of 442 not moving is to be over-run by boreal species sweeping uphill (Figs. 5, S2). Temporal responses 443 may be necessary to withstand the immediate effects of warming, but insufficient longer-term. 444

Thirdly, the pronounced and largely concordant trends in leafing and flowering phenology 445 (Fig. 4B) indicate capabilities of both phenophases to rapidly adjust to interannual variation in 446 447 conditions but also suggests they may be tightly coupled (e.g., Kochmer & Handel, 1986). For example, the delayed emergence of leafing with late snow melt in 2017 was largely mirrored in 448 the timing of flower emergence later in the growing season. Similarly, the early spring of 2018 449 produced closely matched trends for leafing and flowering, including early emergence and faster 450 senescence at lower elevations possibly in response to forest canopy closure. Any form of tight 451 coupling where flowering is dependent on vegetative development may be expected on arctic 452 453 mountains, given their narrow and sometimes harsh and unpredictable growing seasons. On the other hand, the tight coupling of phenophases, especially limited flexibility in flower time, could 454 become problematic with more novel and extreme arctic climates such as summer drought. The 455 456 strength of phenological coupling in arctic flora requires further testing.

There are several caveats to our results. The first is the clear difficulty in accurately
quantifying trends in early emergence, given that the key driver of emergence – snow melt – can
fluctuate interannually by weeks or even months. Indeed, 2018 had the fastest spring snow melt
on the mountain and 2017 the slowest, for the six years of data including 1917-1919. Emergence

times between these two years varied accordingly. Relatedly, the same quantification challenges

- exist with the influence of elevation– interannual fluctuations in phenological performance
- including emergence and senescence interacted strongly with elevation. Many of our species aredistributed across at least two of the three broad vegetation zones (e.g., forest, open alpine,
- summit), such that "early emergence" will likely unfold differently for species by location.
- 466 Finally, even our long-term historical comparisons present potential challenges, in that the year
- 467 of comparison with contemporary trends profoundly shapes analytical outcome. Climatic
- 468 conditions in 1918 happened to be representative of 30-year averages of that era. However, the
- 469 overall trends in climate in the 20th century were non-linear. For example, we would have
- observed significantly different comparative outcomes in phenology if our historical data derivedfrom the 1960s, when conditions were the coldest in the last 110 years.
- 472 There are numerous reports of large and rapid transformation of the diversity and distribution of the high-latitude montane flora, with suggestions that this system may be a bell-473 weather for widespread species loss in ecosystems globally. These projections have been 474 modelled (Niskanen et al., 2019) or based on data that are often lacking in spatial or temporal 475 precision because historical limitations (Myers-Smith et al., 2015). Here, we have full data for 476 477 dozens of species, pulling back the curtain on plant responses over a century. Species have adjusted their distributions profoundly, providing possible temporary resiliency especially 478 against invading southern plant communities. However, with potential limits on phenological 479 480 duration, the downwards contraction of some arctic flora towards areas with the most persistent
- snowbeds, and with recruiting invaders at every point along the gradient, our work powerfully
- demonstrates the complexity of constraints faced by Arctic mountain species that appear
- 483 increasingly squeezed from all sides.

Figure 1. Distributional changes in mean elevation and range width for 83 species along a 900 m 595 596 elevational gradient on Mt. Nuolja Sweden - 1918 versus 2017. Species are grouped based on habitat affiliations of temperature (arctic, boreal) and moisture (broad tolerance, mesic obligate) 597 598 following the maps of Mossberg et al. (Mossberg et al., 1992), and the altitudinal limits of the alpine species given by Heintze (Heintze, 2013), Kilander (Kilander, 1955), and Mossberg & 599 Stenberg (Mossberg & Stenberg, 2018). Arctic species of moister soils (green) are commonly 600 associated with melting snowbeds at our site. The black dots are the mean range and elevation 601 changes of each species, surrounded by 2-dimensional density contours (bivariate nonparametric 602 density) for visualization purposes. Arrows indicate predominant qualitative responses within 603 604 each of the habitat groups.
