Abstract

Background
The negative impact of work has been the traditional focus of GP surveys. We know little about GP positive mental health and psychological resources.

Aims
To profile and contextualise GP positive mental health and personal psychological resources.

Design and Setting
Cross-sectional survey of GPs working in Northern Ireland.

Method
A questionnaire comprising the Warwick Edinburgh Mental Well-being Scale (WEMWBS) and measures of resilience, optimism, self-efficacy and hope and socio-demographic information was posted to 400 GPs randomly selected from a publicly available GP register.

Results
The response rate was 55% (221/400). Mean (SD) value for GP well-being (WEMWBS) was 50.2 (8) compared to UK vets 48.8 (9), UK teachers 47.2 (9) and NI population 50.8 (9). Mean WEMWBS was 2.4 units (95% CI 0.02, 4.7) higher in female GPs compared to males (p=0.05) and 4.0 units (95% CI 0.8, 7.3) higher in GPs over 55 years compared to GPs under 45 (p=0.02). Optimism was 1.1 units higher in female GPs than males (95% CI 0.1, 2.0) and 1.56 units higher in GPs over 55 years (95% CI 0.2, 2.9); hope was 3 units higher in GPs over 55 years (95% CI 0.4, 5.7). Correlation between WEMWBS and psychological resources was highest with hope 0.65 (p=001).

Conclusion
GPs have levels of positive mental health that are comparable to the local population and better than other occupational groups such as vets and teachers. Male and younger GPs may have most to gain from well-being interventions.

Keywords
Primary care; Surveys and Questionnaires; Resilience, Psychological; Optimism.

How this fits in
This survey presents novel insights into positive resources and strengths of GPs. It complements the traditional focus on burnout and stress. In a context of substantial flux, GPs are maintaining levels of positive mental health comparable to the local population. They appear to have good levels of psychological resources particularly with respect to adopting an optimistic and hopeful attitude to life and work.
Introduction

Increasing sub-specialism within secondary care and ongoing demographic shifts highlight the pivotal role that GPs are required to play in the provision of personalised patient care. In the context of rising GP workload and workforce concerns, there is a need to explore the positive resources and strengths of GPs. This positive approach complements the traditional focus on illness, stress, depression and burnout as well as recognising GP resilience as a resource in the context of work pressures. Levels of positive mental health vary across populations and occupational groups (see later). The definition and measurement of resilience continues to be a source of debate (1,2) and empirical evidence for resilience training programmes is limited (3). GPs have expressed ethical-based concerns regarding the recommendation that they should undertake resilience training to adapt to increasingly difficult working conditions (4-6). This paper examines these arguments by measuring GP well-being including resilience and three related psychological resources that are amenable to change and known to impact on work performance (7). More specifically, we assess the profile of positive mental health and level of personal psychological resources among GPs including the nature and degree of variation in GP positive mental health and psychological resources in terms of age, gender, GP practice size and rurality; and then explore the relationships between GP positive mental health and their personal psychological resources.

Method

Participants were identified from a publically available register of GPs compiled by the Business Services Organisation (BSO) in Northern Ireland (NI). The list includes principals and salaried GPs (n=1267) but not training or locum GPs. A random sample of 400 GPs was drawn from this list using a random number generator (8) and in expectation of 50% attrition. A personalised invitation, consent form, information sheet, stamped response-indicating postcard, stamped-return envelope and a questionnaire were mailed to GPs in January 2016. A reminder with replacement questionnaire was mailed in February 2016 to GPs who had not returned a signed, response-indicating postcard. The questionnaire comprised five instruments with good psychometric properties, international validation, and brevity mindful of respondent burden. The WEMWBS has been validated in general populations (9-11) and used to measure positive mental health in occupational groups (12,13). GP personal psychological resources were assessed using the Brief Resilience Scale (BRS) (1,14) the Life-Orientation Test (LOT-R) of Optimism (15,16), the General Self Efficacy (GSE) scale(17) (which addresses the perceived ability to cope with daily hassles and adapt to stressful events) and the Adult State Hope Scale (ASHS) (18). The BRS was chosen because it assesses resilience in terms of being a malleable and modifiable personal resource (19). Information was collected on key socio-demographic variables including broad age categories, gender, practice size and location.

Study size calculation

A standard deviation of 9 (20,21) was used to calculate sample size of 200 based upon determining the true mean WEMWB score in GPs to within +1.2 or -1.2 units. A sample of 200 respondents afforded the detection of a potential difference of 3.75 units in WEMWB scores (with 80% power at the 5% level) between GPs with higher than median practice size compared with lower than median practice size; and the detection of a true correlation of 0.2 between personal psychological resources
Data analysis

The questionnaire data was collected in paper format and entered into SPSS Version 21.0 for statistical analysis. All scales approximated to a normal distribution (see Additional File 1). Means and standard deviations were calculated for the components and overall scores of the WEMWB Scale and the four measures of personal psychological resources (BRS, ASHS, LOT-R and GSE scores) (see Table 1). Independent samples t-tests were used to compare mean scores by gender (male/female), location (urban/rural) and practice size (≤ 4 GPs/≥ 5 GPs). ANOVA was used to compare WEMWB scale by age category (≤44, 45-54, ≥55). Linear regression was used to analyse the increase in WEMWB scale per unit increase in age category and to test for trend; and to determine difference in mean WEMWB scores by categorical variable adjusting for potential confounding by age, gender, location and practice size. R² statistics were calculated for adjusted models. Pearson correlation coefficients (and accompanying p-values) assessed the association between WEMWBS and the four resource scales. Individual missing items within scales were uncommon. Where an item was missing the score for the entire scale was omitted from the analysis. Means and standard deviations were extracted from relevant studies that used each of the five instruments in order to set the results in a comparative international context. The studies were obtained with the help of a specialist librarian using a systematic search of Medline, PsycInfo, and Embase databases (see Additional Files 2 and 3).

Results

Participants

The response rate was 55% and the characteristics of respondents (221/400) were comparable to the study sample and GP population profile with the exception of a higher than expected number of rural GPs who responded (see Additional File 4). The population profile of positive mental health and psychological resources is presented in Table 1. Mean values for each construct were in the top quartile of the scale range. In crude analyses (i.e. not adjusted for confounders) women GPs had higher mean values for positive mental health and for each psychological resource (except self-efficacy) than men, though these differences were not significant. Similarly, rural GPs had higher scores than urban GPs across measures. However, in these crude analyses we did not find any statistically significant differences in well-being and psychological resources between groups based upon rurality and number of partners.

Table 1 here

After adjustment for confounding, women GPs and older GPs had statistically significant higher mean WEMWB scores (see Table 2). Mean WEMWB scores were 2.4 units higher in women compared to men (95% CI 0.02, 4.7) and 4.0 units higher in GPs over 55 compared to GPs under 45 (95% CI 0.8, 7.3). Similar statistically significant findings were observed for optimism (see Additional File 6). The adjusted mean optimism score was 1.1 units higher in women than men (95% CI 0.1, 2.0) and 1.56 units higher in GPs over 55 years compared to those under 45 (95% CI 0.2, 2.9). In the adjusted model, hope scores were 3 units higher in GPs over 55 years compared to those in the 45-
54 age group (95% CI 0.4, 5.7). Statistical analyses did not indicate differences between measured GP characteristics and self-efficacy or resilience scores (see Additional Files 6-9 for further details of adjusted analyses).

Table 2 here

The mean WEMWBS score of GPs in our sample is similar to UK general population samples (9,11,20) and higher than has been identified in occupational groups such as vets(22), university employees(23) and teachers(13) (see Additional File 3). Table 3 shows that each scale or measure of resource was associated positively, albeit moderately so, with mental well-being. The strongest correlation was with hope (r=0.65) whilst the weakest was with self-efficacy (r=0.35). Overall, hope had the strongest relationships with the set of well-being and resource variables including self-efficacy (r=0.48).

Table 3 here

**Discussion**

**Summary**

The paper presents for the first time the positive mental health or well-being of GPs and their level of personal psychological resources. Overall, the positive mental health of GPs was at least comparable to other occupational groups. GPs in the oldest age band (≥55 years) had the highest level of positive mental health, hope and optimism; and women GPs had higher positive mental health and optimism than their male colleagues. A hopeful attitude was the psychological resource that was most strongly related to positive mental health followed by an optimistic outlook.

**Strengths and limitations**

The response rate was relatively low at 55% and the well-being and psychological resource levels of non-respondents were unknown – it is possible that levels may be lower or higher than we have found, for example, respondents may be more (or less) optimistic. However, the response rate was comparable to published GP surveys (24), the sample of respondents reflected the GP population from which the study sample was selected randomly and the sample size had adequate power to be confident about statistical estimates. It was necessary to use wide age bands in order to ensure anonymity. However, anonymity is likely to have moderated potential for social desirability bias (25). Correlation coefficients between positive mental health and measures of psychological resource may have been affected by common method variance (26). The cross-sectional design precluded causal inferences. It might be argued that biases are inherent in self-report measures but there is good psychometric evidence for each measure. Also, the validated instruments have made significant contributions to their respective literatures and afford an opportunity for the survey findings to be interpreted in an international context.

**Comparison with existing literature**

Although the level of positive mental health among the GP sample was lower than reported in previously published UK general population surveys (9,10), it was comparable to the level observed in a recent Northern Irish population survey (11) and higher than levels reported for other occupational groups in the UK such as university employees (23), vets (12) and teachers (13). This
new insight into GP mental health suggests that there may be merit in extending the focus of GP well-being beyond negative constructs such as burnout and stress. Similar to general population survey findings, older GPs had the highest level of positive mental health (10,20), perhaps reflecting a ‘stage of life’ sense of comfortable competency and achievement and perceived positive impact of anticipated retirement. It is interesting to contrast the relatively high level of positive mental health in older GPs with reports that the proportion of GPs aged 55-64 who left practice doubled in the period between 2005 to 2014 (27). Our finding of higher well-being in women GPs contrasts with the results of general population surveys (9,11,28,29) and diverges from recognised gender differences in the prevalence of depression (30). Higher positive mental well-being scores in women GPs may be explained in terms of variables that were not assessed in our study such as different work-time patterns between women and men GPs. For example, role conflict and work-family balance influence well-being (31) and part-time compared to full-time work is associated with higher life satisfaction among career women (32) whilst the relationship between burnout and hours worked is dependent on the extent to which work arrangements meet the needs of doctors, their partners and children (33).

Interestingly, women and older GPs were more optimistic in their outlook than other GPs. U-shaped age variation in optimism has been described in three UK population samples (34). Perhaps unsurprisingly, context and circumstances appear to play a role. For example, one international study found that young, highly educated, affluent Irish women were the most optimistic (35). Our GP sample was more optimistic than general population samples in the UK (34), Portugal (36) and Germany (37) though a higher level of optimism was reported by other occupational groups such as nurses (38) and military personnel (39). Optimism appears to be a significant predictor of physical health outcomes (40-42) including decreased mortality (43) as well as being related to better subjective well-being in times of adversity, higher levels of engagement, coping and being proactive in personal health protection (44). Our finding of a moderately positive association between resilience and optimism concurs with studies of resilience in healthcare (45,46). Positive attitudes including optimism, tolerance, humour and celebrating small gains have been identified as pertinent to resilience in GPs (47-49). ‘Learned optimism’ forms the basis of the Penn Resilience programme (50) highlighting the potential to exploit synergism between these psychological resources. Furthermore, physician resilience has been defined as the ‘ability to invest personal resources in a way that initiates positive resource spirals despite stressful work conditions’ (49). Our finding of a moderately strong correlation between resilience and positive mental health resonates with the concept of a resource spiral and is consistent with evidence that positive emotions promote positive adaptation to adversity (51). Upward spirals generated by positive emotions increase mental flexibility, a commonly identified attribute of resilient individuals (45, 52-55). Normative Brief Resilience Scale scores were higher for health care professionals than our sample and may reflect depleted resources in the face of increasing pressures in General Practice. GPs’ perceptions about their level of general self-efficacy was comparable to other occupational groups including health care professionals (38, 56-58) and higher than general population samples (59-61). Perceived general self-efficacy appears to moderate the effect of daily hassles on positive well-being and negative mental health and is a predictor of positive mental health (61-62). GPs’ relatively higher levels of self-efficacy may point to ways in which to support the GP workforce as self-efficacy and job satisfaction are positively related (63). Hope, too, correlates positively with job satisfaction and work happiness and it is negatively associated with job stress (63-64). Unsurprisingly, hope had the
strongest relationship with positive mental health in our study. Our finding of a high correlation between hope and optimism has been identified in clinical and occupational groups (64,65). Collectively, the results add to evidence about the relationships between psychological resources such as hope and resilience and health and well-being in a work context (66-68). Also, it is likely that this resources-positive mental health-context set of relationships is influenced by other variables such as organisational factors and social networks. A composite construct comprised of hope, optimism, resilience and self-efficacy is associated with higher job satisfaction, less burnout and lower work-related stress in doctors (69-71). Brief and web-based interventions have been shown to develop resources within this composite construct (72-73).

Implications for research and practice

Our findings suggest that younger male GPs may experience lower levels of positive mental health than their older, female colleagues and that they might benefit from support measures designed to improve their well-being such as coaching (74-76) or mindfulness (77-80). The relatively high levels of optimism, hope and positive mental health in older GPs may have implications for morale and recruitment. Since evidence for resilience training (including programme content and format) is limited, a composite approach designed to capitalise on the synergism between related psychological resources simultaneously warrants further investigation.

Conclusion

Overall, the findings indicate that GPs have levels of positive mental health that are comparable to the local population and better than other occupational groups such as vets and teachers. GPs appear to have good levels of psychological resources particularly with respect to self-efficacy and adopting an optimistic attitude to life and work.
