Abstract: The presented work proposes a generalized design methodology for dual-band hybrid antennas. The methodology is applied to a dual-band hybrid antenna system operating in two modes; one allows the antenna to radiate at a lower frequency band, whereas the other operates the antenna at a higher frequency band. The lower band radiating element is also responsible for exciting the higher band radiating element. Since the two radiating modes depend on each other, the antenna system is characterized in detail to achieve efficient impedance matching for both the modes. An efficient model is proposed that models the true behaviour of the system. A hybrid dual-band antenna has been modelled, designed and fabricated. Test results exhibit desired radiation behaviour as well as good impedance match for both the bands. The proposed design methodology allows the design of antenna for each radiating mode quasi-independently. This design methodology can be applied to any similar type of antenna which exploits multiple radiating elements where one is loaded by another.

1. Introduction

With the exponential growth in advanced telecommunication services, there is an ever increasing demand for systems and components supporting multiple standards while being as compact as possible. Embedding multiple functionalities in a single package leads to the concept of system-on-package (SOP). Several designs can be found in literature that propose systems with integrated antenna and front-ends on the same package [1-3].

For designing compact multi-standard systems, front-end antennas remain the most challenging part of any system. Several research works propose multi-functional and reconfigurable antennas [4-6]. In [7-9] different modes are exploited to realize multiple-polarized antennas. Multiple frequency bands can also be achieved by exploiting multiple modes of the same radiating element [10-14]. Although multiple bands can be radiated using same antenna, but there is always a compromise in the radiation efficiency of the antenna system. Multi-band antennas can also be realized through hybrid structures [15-17] with each type of radiating element supporting different frequency band. In order to address the higher data rate requirements, front-ends with large bandwidths are desired. Monopoles, dipoles and Planar inverted-F antennas are used extensively as a solution to this problem. A dipole loaded with dielectric was presented in [18] to achieve wide bandwidth. The integration of such type of structures with the modern high density electronics is a major bottleneck for achieving compact and large bandwidth systems. On the other hand the dielectric resonator antennas (DRAs) offer superior radiation efficiency, higher gain and more compactness that can be used to realize antenna front-ends for high performance systems. In [19] a bulky 3D structure of dielectric loaded monopole antenna was presented. It was focused on the ultra-wideband (UWB) operation of the antenna (i.e. 1-20 GHz) which requires different design approach than the design of narrow band resonant structures. Furthermore, no account of interaction among the different radiation modes was presented in [19].

The presented work thoroughly discusses the design procedure of the dual-band antenna, as well as its coupling and radiation characteristics. The dual-band antenna is formed by combining the broadband monopole and more efficient DRA. A reliable circuit model will be proposed which can be used for co-designing of filter-antenna system as proposed in [20]. The designed antenna system can be used for Wi-Fi applications (IEEE 802.11(a) and 802.11(b)) as shown in [21] in which design concept of a filter-antenna front-end was shown. In this proposed work TE 01δ mode is excited, and will be validated through radiation characteristics of the fabricated antenna. To the authors’ knowledge no significant work has been found in literature that proposes design methodology for such hybrid antennas.

2. Hybrid DRA-Monopole Antenna

The initial dimensions of the antenna structure are computed from the design equations well known in the literature. At first the individual radiating elements are characterized so that models generated can be used for the combined inter-dependent antenna system. The antenna system under discussion consists of two modes, namely the DRA mode, and the monopole antenna mode. The DRA mode will provide the radiation for the upper frequency band centred at f U = 5.5 GHz. The monopole antenna mode will radiate at a lower frequency band which is centred at f L = 2.45 GHz. A split-cylindrical DRA radiating in TE 01δ mode is coupled to a monopole antenna to achieve a dual-
band response. The DRA requires a strong coupling with the monopole antenna, while maintaining the required performance of the overall antenna system. In order to achieve optimal coupling of the DRA mode, an efficient monopole antenna structure is proposed which is optimized for both the modes.

2.1. The DRA Mode

A split-cylindrical—a cylinder cut into half by a plane along its rotational axis—dielectric resonator antenna is chosen for the DRA mode radiation. This structure supports the desired TE$_{01\delta}$ mode. For the DRA mode this particular structure and mode is selected due to its ability to efficiently couple to the monopole antenna. Consider a split-cylindrical shape dielectric resonator antenna of diameter $d$ and height $h$, as shown in Fig. 1(a). The resonator is placed on an infinite ground plane. The field distribution, for TE$_{01\delta}$ mode, inside the dielectric resonator is shown in Figs. 1(b) and (c). The material and dimensions of the dielectric resonator are chosen so as to achieve the required impedance bandwidth. The impedance bandwidth is a function of material's relative permittivity $e_r$ and the aspect ratio (diameter ‘$d$’ to height ‘$h$’ ratio) [22]. Choosing a dielectric material, made of Alumina (tan $\delta$ = 0.002), of relative permittivity $e_r = 9.5$, $d = 18$mm and $h = 6$mm, the DRA will yield an impedance bandwidth of >10%.

The resonant frequency of the DR can be found from [23]. For a full cylindrical DR the resonant frequency is found to be 5.79 GHz. In order to investigate the radiation and impedance characteristics of the TE$_{01\delta}$ mode the structure shown in Fig. 1(a) is simulated. It can be observed from Fig. 1 that the desired mode is efficiently excited in the DR.

2.2. The Monopole Antenna Mode

Radiation in the lower frequency band is realized through a folded monopole antenna structure which is excited through a grounded coplanar waveguide feed, as shown in Fig. 2. The antenna is matched through a quarter wave transformer. For this structure the substrate is chosen to be Rogers RT5880 having $e_r = 2.2$ and height of the substrate is 1.575mm. The length of the monopole can be approximated as $l_1 + l_2 = \lambda_g/4$ (Fig. 2). The ground plane of the monopole antenna influences the gain, impedance and the resonant frequency, therefore it must be large enough and the open end of the monopole must be sufficiently spaced from the ground. Fig. 2 shows good impedance matching of the folded monopole antenna configuration.

![Fig. 2. Return loss of the monopole antenna. Structure for monopole antenna mode (bottom left inset). Input impedance of the antenna (bottom right inset).](image)

![Fig. 3. Radiation patterns (Gain vs $\theta$). $\phi = 0^\circ$ (x-z plane) in solid red, and $\phi = 90^\circ$ (y-z plane) in dashed green (a) DRA mode, (b) Monopole mode](image)
The radiation patterns of the simulated antenna structures are illustrated in Fig. 3. These patterns will be used as a reference and will be compared with the radiation patterns of the final structure.

2.3. Combined Antenna System

The two antenna systems (DRA and the monopole antenna) are investigated separately, both are designed in such a manner so that they are compatible with each other. The dielectric resonator is now placed, as shown in Fig. 4(a) and (b), on the designed monopole structure to achieve a dual-band antenna.

![Combined DRA-Monopole antenna system. (a) Top View, (b) Side View, (c) Plot of E fields for TE_{01δ} mode, inside the dielectric structure, (d) Plot of H fields TE_{01δ} mode, inside the dielectric structure. The fields are shown at the cut-planes passing through the dielectric resonator.](image)

Observing the E and H fields inside the dielectric resonator (Fig. 4(c) and (d)), it can be verified that the TE_{01δ} mode is excited in the DR at high frequency (DRA mode).

It can be observed from Fig. 5 that when the shape of the dielectric material is changed the DR mode is changed significantly whereas there is negligible change in the monopole mode.
It is evident from Fig. 5(c) that the change in relative permittivity allows the change in DRA mode without affecting much to the monopole mode.

The proposed antenna structure exhibits dual radiating modes that can be designed independently, where one mode provides the coupling mechanism for the other without much affecting on its radiation characteristics.

3. Coupling Characteristics

In order to properly model the whole antenna system, first individual antenna elements are characterized by simulating their input impedances for similar feeding structures as detailed in the previous section. The element values extracted for a particular resonating mode will remain same for the combined model this can be verified from the full-wave simulation of the combined structure. This section will detail the coupling characteristics as a function of position of DR on the monopole which will depend on the surface current distribution on the monopole, which eventually leads to the extraction of coupling coefficients. The monopole antenna, coupled to the source through quarter wave impedance transformer, shown in Fig. 2 can be modelled as a parallel resonant circuit as illustrated in Fig. 6(a). For parallel resonant circuit, loaded quality factor $Q_d$ for monopole mode is given by:

$$Q_m = \frac{R_m}{a_{0L}} = \frac{f_0}{f_{90} - f_{90}}$$ (1-a)

$$N_{md}^2 = \left(\frac{1}{R_{tm}} - \frac{1}{R_d}\right)Z$$ (1-b)

$R_{in}$ is the equivalent resistance of parallel RLC coupled to source. $f_0$ is the resonant frequency and $f_{90}$ are the frequencies at which phase of $S_{11}$ is 90° above and below $f_c$ (from filter theory). The extracted circuit model values are: $N_{sm} = 1.6, R_m = 27 \Omega, L_m = 1 \text{nH}, C_m = 5.44 \text{pF}.$

Simultaneously for DRA mode loaded quality factor is $Q_d$ and $R_{ld}$ is the equivalent resistance of parallel RLC as defined by (2). The coupling $N_{sm}$ is realized through a quarter wave transformer. The coupling $N_{md}$ is a function of the position of DR on monopole antenna. The coupling $N_{md}$ can carefully be optimized by studying the surface currents on the monopole, at both the frequency bands – centred at $f_l$ and at $f_c$. It is evident that more the DR covers the monopole area, where electric fields are maximum, more predominate will be the loading effect on the monopole mode (at $f_l$). A structure is therefore proposed which caters for such an effect. Fig. 7, shows the surface current distribution on the monopole antenna at $f_l$. This structure is less sensitive to the effects of DR at $f_c$, as the DR does not cover the portion of maximum E field. As can be seen from Fig. 7 the maximum current is in the unfolded (along y-axis) branch, the radiation pattern is similar to the ideal monopole as illustrated in Fig. 3(b). As the DR is over the area of monopole where electric field is strong the DR is tightly coupled to the source at upper frequency band $f_c$. The DR is placed on the monopole antenna, as shown in Fig. 7(c), where the maximum coupling for the TE$_{015}$ mode is achieved.

The arrows show the equivalent short electric monopoles (for the monopole antenna mode), (c) Surface current distribution on the structure with DR at 5.5 GHz. The arrow shows the equivalent short magnetic dipole (for the TE_{01δ} DRA mode).

Consider three different configurations of the antenna system as shown in Figs. 8(a), (b) and (c) which differs by the placement of DR on the monopole antenna. The input impedances for the three configurations are detailed in Fig. 8(d), the extracted quality factors are shown in Fig. 9(a) and subsequent extracted element values for the proposed circuit model are given in Table 1, where \( R_m = 27 \, \Omega, \quad L_m = 1 \, \text{nH}, \quad C_m = 5.44 \, \text{pF} \).

The return losses for each of the configurations are shown in Fig. 9(b). It is evident that for configuration \( a \) and \( b \) the desired mode of the dielectric resonator is coupled to the source. It can also be seen from Fig. 9(b) that the DR is not coupled to the source for configuration \( c \).
Fig. 10(a) shows the input impedance of the hybrid antenna system, the proposed model (Fig. 6(b)) approximates the optimized antenna accurately with elements values given in Table 2.

The gain of the antenna is shown in Fig. 10(b). The efficiency of the antenna for the monopole mode is 95% and for the DRA mode is 96%.

4. Results and Discussion

The combined DRA-Monopole antenna structure has been optimized and developed (Fig. 11). The dielectric resonator having \( \varepsilon_r \) of 9.5 and dimensions, \( d = 18 \text{mm} \) and \( h = 6 \text{mm} \) is attached to the PCB with a conducting glue. The PCB material chosen here is Rogers RT5880 having \( \varepsilon_r = 2.2 \) and substrate height of 1.575 mm. The simulated and measured return loss of the dual-band hybrid antenna system is illustrated in Fig. 11. As it can be seen from Fig. 11 the measured lower frequency band is moved from the desired frequency band, this was due to the imperfection in the fabrication of prototype. Nevertheless the dual-band phenomena can well be studied with this structure.

The simulated and measured radiation patterns, as shown in Figs. 12(a) and (b), at the lower frequency band \( f_L \) the results show good similarity although 3-5 dB loss is observed (for \( \phi = 0^\circ \)) in the measurement results. A little deterioration is observed in the radiation pattern at \( \theta = 180^\circ \)– back side of the DR (for \( \phi = 90^\circ \)). At the upper frequency band centred at \( f_U \) the radiation patterns of the simulation and the measurements can be compared from Figs. 12(c) and (d). The patterns for the band at \( f_U \) can be compared with that of Fig. 3. The patterns are quite similar except where the effect due to finite ground plane is dominant, which is more clear in the plot of \( \phi = 0^\circ \) plane. Comparing Fig. 3(a) and Fig. 12(c) it can be observed that the two nulls appearing in Fig. 3(a) at \( \theta = 90^\circ \) and \( \theta = 270^\circ \) cannot be seen in...
The proposed methodology can be employed to design any antenna system, for example, monopole can be replaced by a patch antenna, and the same principle could be followed to extract the model parameters. In that case, the desired patch antenna mode will be characterized for coupling with the DRA mode as well as with the source. Similarly, the DRA will be analysed for its dependence on the patch antenna mode, which will then be coupled to the source. Once all the model parameters are known, the complete antenna system can easily be designed. Furthermore, this methodology can be extended to multiple radiating modes (more than two) that may couple to each other in complex coupling topologies. The model derived from the above procedure can be used to integrate with other front-end components or co-designing of subsystems exhibiting multiple functionalities such as filter-antenna or antenna-amplifier subsystems. The design process is systematically summarized below:

Step 1. Characterize the elements starting with the element having less couplings and moving towards those with more couplings.

Step 2. Analyse the results and find the variables and structure to achieve quasi-independent design of each radiating mode.

Step 3. Extract the model parameters for each radiating mode based on the analyses from the previous step.

Step 4. Optimize the combined system. The generated model can now be used, reliably, to optimize the whole multiband radiating system.

Step 5. Integrate the optimized model with the rest of front-end components. The generated model can now easily be integrated with other circuit elements, which consequently simplifies the hybrid (EM + circuit) system design process.

5. Conclusion

A detailed designed methodology for dual-band antennas has been proposed. The proposed methodology is employed for designing a dual-band hybrid DRA-Monopole antenna. Since the hybrid antenna consists of two interdependent radiating elements, a comprehensive coupling analysis has been presented. A reliable circuit model has been proposed which caters for the off-resonance loading effect on both the modes (monopole antenna mode and the DRA mode). It has been demonstrated that the two hybrid radiating modes can be designed quasi-independently. The proposed design methodology simplifies the design procedure for complex radiating systems.
