22 like receptor 4; TNF, tumor necrosis factor.

23 **Keywords:** FADS1, FADS2, genotype, linoleic acid,

24 **Abstract**

25 **Scope:** This study examined to what extent plasma linoleic acid (LA) is modified by adiposity,
26 and explored any association between plasma LA, demographics, dietary intakes, markers of
27 metabolic health and haplotypes of the fatty acid desaturase (FADS) 1/2 genes.

28 **Methods and results:** 820 participants with fasting blood samples from Irish National Adult
29 Nutrition Survey were studied. Plasma fatty acids were determined using GC-MS. 15 SNPs of
30 FADS 1/2 genes were genotyped. Plasma LA decreased while γ-linoleic acid and dihomo-γ-
31 linoleic acid increased in overweight/obese participants ($P \leq 0.002$). Participants in the highest
32 quartile of plasma LA showed decreased plasma markers of *de novo* lipogenesis, insulin resistance
33 and of inflammation (TNF-α, PAI-1) ($P \leq 0.005$). Adiposity (waist circumference and body fat) was
34 strongly inversely associated with plasma LA accounting for 11.8% of variance observed, which
35 was followed by FADS1/2 haplotypes (3.9 %), quantity and quality of carbohydrate intakes
36 (3.8 %), dietary PUFA intakes (3.7 %), systolic blood pressure (3.6 %) and age (3.2 %).

37 **Conclusion:** Plasma LA was inversely associated with adiposity, followed by haplotypes of
38 FADS1/2 genes, carbohydrate intakes and dietary PUFA intakes. The association observed
39 between plasma LA and adiposity may be linked to decreased *de novo* lipogenesis, insulin
40 resistance and inflammation.

41

42 **Introduction**

43 The essential fatty acid, dietary linoleic acid (LA) has traditionally been considered as protective
44 against cardiovascular disease (CVD) [1] and coronary heart disease (CHD) [2, 3]. Randomized
45 controlled trials suggest that diets high in PUFA may result in lower fat accumulation relative to
46 other fatty acids [4, 5]. A number of observational studies have also attempted to relate circulating
47 or plasma LA to health outcomes. In healthy adults, two recent studies which completed pattern
48 analysis of a suite of plasma and erythrocyte fatty acids identified patterns rich in LA, both of
49 which were associated with healthier phenotypes [6, 7]. The Epic Interact Study reported a strong
50 inverse association between plasma linoleic acid and type 2 diabetes incidence [8]. Other studies
51 in older populations or those at risk of CVD have suggested that circulating LA is inversely related
52 to adiposity [9, 10], central adiposity [5, 11] and risk of the metabolic syndrome and type 2 diabetes,
53 but not CHD [12, 13]. In a middle-aged community cohort, half of whom were obese, erythrocyte
54 LA was inversely related with insulin resistance measured by HOMA score and IL-6 [11].
55 However any relationship between plasma LA and health may be influenced by body weight status,
56 with initial reports suggesting that circulating LA is positively related to circulating concentrations
57 of soluble intercellular adhesion molecule-1 in (ICAM, a marker of endothelial activation and
58 predictor of future CVD events) obese participants, the opposite being observed for normal weight
59 adults [6]. Beyond this, little is known in terms of to what extent circulating LA level is associated
60 with adiposity and how circulating LA is related to other markers of inflammation and metabolic
61 health, particularly in younger, healthy cohorts.

62 The enzymes Δ-5 and Δ-6 desaturase, encoded by fatty acid desaturase (FADS) 1 and 2 genes, are
63 the rate limiting enzymes regulating synthesis of long-chain n-6 polyunsaturated fatty acids (PUFA)
64 such as the conversion of LA to γ-linoleic acid (GLA, 18:3n-6), dihomo-γ-linoleic acid (DGLA,

65 20:3n-6) and arachidonic acid (ARA, 20:4n-6). Using genotype and haplotype analysis, circulating
66 LA levels were associated with FADS 1 and 2 genes [14-16], with carriers of minor alleles
67 demonstrating increased circulating LA [17]. Generally, the interaction between adiposity, dietary
68 intakes, circulating LA and haplotypes of FADS1/2 genes and how any interaction may affect
69 markers of inflammation and risk of metabolic syndrome (MetS) remain largely unknown. Against
70 this backdrop, the objective of present study was to explore, in a cohort of healthy Irish adults, the
71 association between plasma LA and adiposity, demographics, dietary intakes and haplotypes of
72 FADS1/2 genes.

73

74 **Participants and methods**

75 Design and population

76 This paper uses data from the cross-sectional national food survey of Irish adults: the National
77 Adult Nutrition Survey (NANS) [18]. The NANS (May 2008-April 2010) examined the habitual
78 food and beverage intake of a representative sample (n=1500, 740 males and 760 females) of Irish
79 adults aged 18-90 years who were free-living and who were not pregnant or breast feeding. Ethical
80 approval was obtained from University College Cork Clinical Research Ethics Committee of the
81 Cork Teaching Hospitals and the Human Ethics Research Committee of University College Dublin
82 (ECM 3 (p) 4 September 2008). All procedures in this study were in accordance with the guidelines
83 laid down in the Declaration of Helsinki, with written informed consent obtained from all
84 participants.

85 As no national identification system exists in the Republic of Ireland, hence participants were
86 randomly selected from the Data Ireland (National Postal Service) database of free-living adults

87 in Ireland in 20 geographical clusters nationwide, with clusters selected to provide proportional
88 representation across the urban-rural continuum and a minimum of 100 participants in the least
89 populated age and sex subgroups. A sample of 1500 free-living adults, representing the Irish
90 population of over 4 million people participated in the dietary survey with analyses of the profile
91 of NANS showing it to be representative of adults in Ireland with respect to age, gender, social
92 class and urban/rural location compared to the most recent Irish census [18-20]. The overall
93 response rate was 60%. In the present paper, only participants for whom fatty acid profiles were
94 available and valid reporters are included, leaving a final sample size of 820 (which remained
95 representative of the entire cohort). Demographics of participants who provided fasting blood
96 samples were reported elsewhere [20].

97

98 Dietary assessment

99 Food and beverage consumption was assessed using a 4-day semi-weighed food record. Initial
100 nutrient analysis was carried out using the Weighed Intake Software Program (Tinuviel Software,
101 Anglesey UK), which uses data from McCance & Widdowson's The Composition of Foods, fifth
102 and sixth editions plus all nine supplemental volumes as described elsewhere [18] to generate
103 nutrient intake data. Adjustments were made to the food composition database to take account of
104 recipes, nutritional supplements, commonly consumed generic Irish food and new foods on the
105 market. All entries were double-checked by the researcher and a random sample was checked by
106 another researcher in-house to minimize the chance of error.

107

108

109 Plasma fatty acids analysis

110 The procedures used to determine plasma fatty acids profiles in the fasted samples are described 111 elsewhere [6]. In brief, plasma lipids were extracted using the method of Bligh & Dyer [21]. 112 Butylated hydroxytoluene (BHT) and heptadecanoic acid (2 mg/mL in methanol) were used as 113 antioxidant and internal standard, respectively. Extracted plasma lipids were transesterified using 114 boron tri-fluoride-methanol solution (14%), and the resulting fatty acid methyl esters (FAME) 115 were extracted twice using hexane and water [22]. FAMEs were separated and identified by gas 116 chromatography coupled with mass spectrometry (GC-MS) HP 5890 Series II, HP 5971A (Hewlett 117 Packard) using an Omegawax 250 fused silica capilary column (30m×0.25mm×0.25μm film 118 thickness, (Supelco). 38 known peaks were identified (including 17:0 as internal standard) using 119 GC-MS. Laboratory CV of LA in fasting blood samples was 14.4%. The demographics of 120 participants who provided a blood sample (76% of total sample), and those in the entire sample 121 have been reported elsewhere, with no significant differences identified [19].

122

123 Assessment of biochemical profiles and metabolic risk factors

124 Collection of anthropometric measurements (including weighed body weight, BMI, waist 125 circumference, body fat and blood pressure) and biochemistry parameters assessment has been 126 described elsewhere [23, 24]. In brief, anthropometric measurements were carried out in duplicate 127 by trained researchers using standardized methods. % body fat and weight were collected using 128 Tanita ® Model BC-420 MA body composition analyzers (Tanita Ltd. GB) with a % CV of 0.73% 129 and 0.02% respectively. Height was measured using a Leicester portable height measure (Seca, 130 Birmingham, UK). All scales were calibrated and placed on a hard surface prior to use with 131 participants asked to remove any heavy clothing, accessories or shoes as appropriate. Hip and waist

132 circumference were measured using non-stretch measuring tape to the nearest 0.1cm with % CV
133 of 0.17% and 0.13% respectively. Weight class was created as normal weight (BMI < 25 kg/m^2),
134 overweight (BMI 25-30 kg/m^2) and obese (BMI > 30 kg/m^2). Blood samples were collected by
135 venepuncture by trained phlebotomists and stored appropriately until they reached the lab within
136 5 hours of collection for processing and further storage at -80^0C until further analysis. Biochemical
137 values were assessed using a clinical bioanalyzer (Randox Daytona, Randox Laboratories) and
138 cytokines and hormones using a biochip array system (Evidence Investigator, Randox Laboratories)
139 except adiponectin which was measured by ELISA (ALPCO Diagnostics Kit). All samples were
140 run in duplicate with standard quality control procedures followed in both analyses to ensure data
141 integrity. Homeostatic model assessment-IR (HOMA-IR) score was calculated using the formula
142 (fasting insulin µU/mL x fasting glucose mmol/L)/22.5 [25]. Quantitative sensitivity check index
143 (QUICKI) score was calculated as follows: 1/(log(fasting insulin µU/mL) + log(fasting glucose
144 mg/dL) [26]. Diagnosis of MetS was defined according to the National Cholesterol Education
145 Programme's Adult Treatment Panel III criteria for MetS 2001 [27] including fasting blood
146 glucose concentrations of 5.5-7.0 mmol/L, serum triacylglycerol (TAG) concentrations of ≥1.7
147 mmol/L, HDL<1.0 mmol/L (men), <1.3mmol/L (women), blood pressure ≥130/85mmHg and
148 waist circumference >102cm (men) & >88cm (women). Physical activity was estimated using a
149 tri axial accelerometer (Actigraph GT1M, ActiGraph, LLC) for the four days of the survey period
150 [28].

151

152 Genotyping

153 15 single nucleotide polymorphisms (SNPs) were selected based on previous studies which have
154 been shown to be associated with circulating LA [14, 16, 29] and human health [30]. SNP

155 genotyping was then conducted by the LGC group (www.lgcgroup.com) using their proprietary
156 KASPar polymerase chain reaction technique [31].
157
158 Statistical analysis
159 Plasma n-6 PUFA (18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6) profiles were compared
160 across normal weight, over-weight and obese participants. Quartiles of plasma LA, GLA and
161 DGLA were obtained using SPSS version 20.0 (IBM Inc. Chicago, USA). General linear contrast
162 model adjusted for age, body fat, blood pressure, waist circumference, waist hip ratio, smoking
163 status, working energy expenditure, and BMI was applied across plasma LA quartiles for
164 comparison of percentage of plasma fatty acid, nutrient density (calculated as % total energy (TE)
165 or µg or mg/10MJ), and circulating concentrations of biochemical biomarkers. Differences in
166 gender, social class, smoking habits, contraceptive use and metabolic risk factors across quartiles
167 were compared using Chi-square test. Δ-5-desaturase (D5D) and Δ-6-desaturase (D6D) were
168 estimated using fatty acid product/precursor ratios as following: D6D=C18:3n-6/C18:2n-6, and
169 D5D=C20:4n-6/C20:3n-6 [32]. Contraceptive use in females was not controlled for in subsequent
170 analysis due to the low proportion (3.5 %) of oral contraceptive users in NANS with no difference
171 in proportions across LA quartiles (*P*=0.094). One-way ANOVA was also applied across fatty acid
172 clusters for demographic variables including age, BMI, waist circumference, body fat physical
173 activity, waist hip ratio, and blood pressure. Skewed data were log transformed to obtain
174 normalized distribution. Where appropriate in this exploratory analysis, Bonferroni correction was
175 applied by adjusting the p-values by the number of traits in each table. p-values that exceed 1.0
176 after correction for multiple testing have been marked down to 1.000.
177

178 Linkage disequilibrium (LD) was assessed using Haploview 4.2 [33], and haplotype blocks were
179 obtained using the Gabriel's definition [34]. Haplotype frequency was estimated using Haplo.Stat
180 1.7.6 package in R 3.2 (R Foundation for Statistical Computing, Vienna, Austria; ISBN 3–900051-
181 07–0; Internet: http://www.R-project.org). Multiple linear regression with stepwise backward
182 selection was used to explore possible determinants of plasma LA status. Demographic and dietary
183 intake variables were included in the initial model and haplotypes were included in the final model
184 regardless of the significance. Partial R^2 was used to calculate the explained variation of each
185 determinants in the final model. The association between plasma LA and haplotypes were
186 estimated using HapStat 3.0 [35].

187

188 **Results**

189 A complete fasting plasma fatty acid dataset of 820 participants (mean age 41.9 ± 16.7 years, with
190 412 males and 408 females) were included in the analysis. Initial examination showed that plasma
191 LA and estimated Δ-5-desaturase activity decreased while GLA, DGLA, and Δ-6-desaturase
192 activity increased across the body weight categories in Irish adults ($P \leq 0.003$) (Table 1).
193 Demographics and markers of metabolic health were compared across the quartiles of plasma LA
194 (Table 2 and Table 3), GLA and DGLA (Table S1) to explore any association between plasma LA,
195 GLA, DGLA and health parameters. As quartiles of plasma LA showed greater separation in terms
196 of demographics and markers of metabolic health (as described below) therefore subsequent
197 analysis focused on plasma LA only.

198

199 Demographics and dietary intakes

200 As shown in Table 2, participants in the highest quartile of plasma LA displayed a healthier
201 phenotype. Compared with participants in quartile 1 (Q1), participants in quartile 4 (Q4) were
202 younger (50.7 years *vs.* 36.5 years, $P<1.9 \times 10^{-19}$), with lower adiposity (including BMI, body fat,
203 waist circumference and waist hip ratio, $P<3.1 \times 10^{-6}$), blood pressure (131.9/81.4 mmHg *vs.*
204 118.2/75.3 mmHg, $P<2.2\times10^{-7}$), metabolic risk and a lower proportion were overweight (45.3 %
205 *vs.* 32.1 %) or obese (34.7 % *vs.* 14.0 %) ($P \leq 2.7\times10^{-7}$). Higher work activity energy expenditure
206 was observed for Q4 (47.8 MET hrs/wk vs. 66.1 MET hrs/wk, $P<0.026$) and a greater proportion
207 of participants that never smoked (41.9 % *vs.* 62.7 %, $P<0.001$). Dietary intakes across the quartiles
208 of plasma LA are shown in Table S2. Across plasma LA quartiles, intake of starch, PUFA, n-6
209 PUFA and dietary fibre significantly increased ($P < 0.003$).

210

211 Markers of metabolic health and plasma fatty acids

212 The clinical chemistry biomarkers and plasma fatty acid levels across quartiles are shown in Table
213 3. After adjustment for confounders, insulin, C-peptide, TAG, HOMA-IR, PAI-1, TNF-α, hs-CRP
214 decreased, while QUICKI and adiponectin increased across plasma LA quartiles ($P\leq0.005$).
215 Regarding plasma fatty acids related to the n-6 PUFA pathway, 20:2n-6, 18:3n-6, 20:3n-6 and
216 D6D decreased across plasma LA quartiles ($P \leq 0.019$), whereas total n-6 PUFA and n-6/n-3 ratio
217 increased ($P\leq1.4 \times 10^{-138}$). Plasma total SFA and total MUFA decreased ($P \leq 1.1 \times 10^{-21}$), as did
218 plasma fatty acids related to *de novo* lipogenesis (DNL, including 14:0, 14:1n-5, 16:0, 16:1n-7 and
219 18:1n-9) were also significantly decreased ($P\leq4.7\times10^{-6}$) across plasma LA quartiles.

220

221

222 Effects of haplotypes on plasma n-6 PUFA profiles

223 The degree of LD between the analyzed genetic polymorphisms are shown in Figure S1.
224 Haplotypes were statistically reconstructed for three windows (Table 4). The first window
225 contained all 15 SNPs from rs174537 to rs482548. Seven haplotypes were identified in this
226 window with a frequency over 1 %, of which haplo 7 was the most common (53.9 %) haplotype
227 with no minor allele. Compared with haplo 7, haplo 1, 3, 4, 5 were positively associated with
228 plasma LA ($P \leq 0.02$), with all of the haplotypes except haplo 2 negatively associated with D5D
229 and D6D ($P \leq 6.44\times10^{-3}$) (Table 5). The second window contained 8 SNPs from rs174537 to
230 rs99780, and four haplotypes were reconstructed with frequency above 1 %. Compared with the
231 most common haplotype (haplo 4 with frequency of 65.6 %) in the second window, all the other
232 haplotypes were positively associated with plasma LA while negatively associated with D5D and
233 D6D ($P \leq 1.67\times10^{-3}$). The third window contained 3 SNPs from rs2524299 to rs174583, and three
234 haplotypes were reconstructed with a frequency above 1 %. Compared with the most common
235 haplotype (haplo 3 with frequency of 65.5 %) in the third window, all of the other haplotypes were
236 positively associated with plasma LA while negatively associated with D5D and D6D ($P \leq$
237 1.64×10^{-3}). Haplotypes in the second and third windows explained the variance of plasma LA by
238 3.5 %, respectively (Table S2 and Table S4). We also explored the interaction of dietary PUFA
239 intakes and haplotypes but no significant interaction was found after adjustment for confounders
240 ($P \geq 0.057$).

241

242 Possible determinants of plasma LA

243 Multiple linear regression of possible determinants of plasma LA are shown in Table 6. Of the
244 variables tested, adiposity measures (waist circumference and body fat) were most strongly

245 inversely associated with plasma LA accounting for 11.8 % of the total variance, followed by 15-
246 SNP haplotypes (3.9 %), quantity and quality of carbohydrate intakes (3.8 %), dietary PUFA
247 intakes (3.7 %), systolic blood pressure (3.6 %) and age (3.2 %).

248

249 Discussion

250 In this study, higher plasma LA was related to a healthier phenotype and metabolic profile in Irish
251 adults. We observed an inverse relationship between plasma LA and the adiposity measures
252 studied, with waist circumference and body fat most strongly associated with plasma LA, followed
253 by dietary PUFA and haplotypes of FADS genes. The beneficial effects of plasma LA may be
254 associated with decreased biomarkers of DNL, insulin resistance and inflammation, all of which
255 have previously been linked with the pathogenesis of obesity [36, 37].

256 A growing body of evidence suggests that LA may influence health outcomes. An inverse
257 relationship between serum LA and all-cause mortality (but not CVD risk) has been described in
258 a cohort of healthy older adults [38]. Further observational studies report lower plasma
259 phospholipid LA and higher GLA and DGLA levels in overweight/obese adolescents [9, 39] and
260 higher proportions of serum and cholesterol ester LA being associated with lower markers of
261 abdominal obesity and BMI and reduced T2D incidence [8, 40-42]. Altered desaturase activity is
262 documented in overweight and obese participants and those with T2D, with reports of elevated
263 D6D and decreased D5D [8, 9, 39, 41]. Growing evidence suggests that such benefits may arise
264 from effects of LA on body fat accumulation. Animal trials and human RCTs indicate that
265 compared to SFA, high LA intakes result in improvements in body composition outcomes [4, 5,
266 43]. There is some evidence of similar benefits in populations with regular dietary LA intakes
267 whereby serum or erythrocyte LA was inversely related to body fat, specifically trunk fat in a

268 healthy elderly cohort [5] and in a middle aged relatively healthy cohort [11]. Of interest, such
269 benefits were not observed for erythrocyte n-3 PUFA or for the MUFA, OA [11]. In the present
270 study, we confirm these fatty acid profiles of elevated LA and altered patterns of D5D and D6D
271 activity according to body weight status and without significant alterations in n-3 PUFA status, in
272 this nationally representative cohort of healthy adults aged 18-90 y. Our study adds to evidence
273 which is suggestive of either a protective effect of circulating LA on obesity and/or, of altered fatty
274 acid metabolism in the presence of excess body weight. However, desaturase activities based on
275 ratio of circulating fatty acids are indirect measure of enzyme activities which may also be affected
276 by lifestyle. Further, our results are presented as percentage, rather than absolute, values which
277 may imply co-dependence on all other fatty acids. Further research is required to explore the
278 specific health implications of plasma LA as well as any interactions between dietary PUFA
279 intakes and circulating fatty acid profiles.

280 Previous studies have demonstrated a similar inverse association between circulating LA and
281 biomarkers such as insulin, glucose, TAG, hs-CRP, with higher adiponectin concentrations and
282 with reduced risk of insulin resistance, metabolic syndrome, cardio-metabolic risk score and T2D
283 [5, 8-10, 44-46]. In addition, our results show decreased inflammation markers such as PAI-1 and
284 TNF-α across plasma LA quartiles, elevated levels of which have been linked to obesity [47].
285 Nevertheless, this decrease in markers of metabolic health in the present study remained significant
286 even when controlling for BMI and waist circumference. A negative association between plasma
287 LA and inflammation markers e.g. IL-6 and CRP has been reported elsewhere [11, 48]. Such
288 associations may be explained by a recent study, showing that LA may suppress the expression of
289 toll-like receptor 4 (TLR4), phosphorylation levels of c-Jun amino-terminal kinases (JNK) and
290 agouti-related protein (AgRP) [49]. AgRP promotes food intake[50], and an absence of JNK1 may

291 lead to decreased adiposity and improved insulin sensitivity [51]. Such potential mechanisms may
292 help explain the decreased adiposity and markers of inflammation observed in participants in the
293 highest quartile of plasma LA (Q4). Moreover, bioactive metabolites of LA such as nitro-linoleic
294 acid may be anti-inflammatory by reducing the activation and gene transcription of nuclear factor-
295 κB while stimulating activation of peroxisome proliferator–activated receptor γ [52]. Further
296 research is required in this area.

297 It is possible that the decreased plasma LA observed in overweight/obese participants in our study
298 may be linked to DNL. DNL is a, typically inhibited, pathway of converting excess carbohydrate
299 to esterified fatty acids which are subsequently stored as TAG in the liver and adipose tissue [53].
300 Increased DNL has been observed in the obese [36, 54], in non-alcoholic fatty liver disease [55]
301 and under conditions of insulin resistance, including inflammation [53]. Further, DNL stimulated
302 hepatic TAG are reported to be enriched with palmitic acid while depleted in LA [56]. In our study,
303 in addition to decreased levels of plasma LA observed in obese participants, all adults in the lowest
304 quartile of plasma LA had a fatty acid profile suggestive of DNL (i.e. reduced LA, increased 14:0,
305 16:0, 16:1n-7) and with patterns of biochemical markers suggestive of insulin resistance and low-
306 grade inflammation. Dietary intakes may also influence DNL, whereby high carbohydrate, low
307 fat diets may promote DNL, particularly when dietary sugar is substituted for starch [57]. In
308 contrast high dietary fibre intakes can yield less short-chain fatty acids, which may suppress DNL
309 and improve insulin sensitivity [58, 59]. In our study, participants had a relatively high fat diet
310 (mean daily intake of 33.8 %TE) and moderate carbohydrate intakes (mean daily intake of
311 42.6 %TE). Nevertheless, participants with the lowest circulating plasma concentrations (quartile
312 1) had lower intakes of starch and dietary fibre, while regression analysis identified quantity and
313 quality of carbohydrate intake as the third largest determinant of plasma LA (3.8%). Collectively,

314 in this cohort of generally healthy adults there exists a group with lipid and metabolic profiles
315 suggestive of possible future risk and who can be easily identified by nature of circulating plasma
316 LA concentrations. This is supportive of the hypothesis which aims to clarify whether endogenous
317 metabolites or lipids constitute simple and effective biomarkers of metabolic diseases such as
318 NAFLD, type 2 diabetes and metabolic syndrome [6, 55].

319 Polymorphism and haplotype of FADS1/2 genes have been reported to be linked to long-chain
320 PUFA concentrations/metabolism such as for LA, ARA, D5D and D6D [14, 30, 60, 61]. To our
321 knowledge, only one study reported variation of haplotypes of FADS genes in relation to serum
322 phospholipid , which was higher compared with the present study (9.2 % *vs.* 3.9 %) [14]. This may
323 due to different SNPs, lipid fractions and study population included. Potential dietary PUFA
324 intakes × haplotypes interactions were also explored in the present study, however, the P values
325 were above the significant threshold ($P \geq 0.057$) after adjustment for confounders [62]. The impact
326 of dietary intakes × haplotypes/genotype interactions on circulating n-6 PUFA profiles have been
327 poorly explored and merits future study [63]. Haplotype analysis of FADS genes also revealed
328 significant association between haplotypes and concentration of hs-CRP and TAG [15, 16].
329 Similarly, results of genome-wide association studies reported that carriers of the minor allele of
330 rs174537 and rs174547 showed lower total cholesterol HDL-C and LDL-C [64, 65]. However, no
331 significant association was identified in our study between haplotypes and inflammation markers,
332 suggesting that haplotype may not be involved in the association between plasma LA and
333 inflammation.

334 The major strength of the present study is that we included a comprehensive group of inflammation
335 markers, genotype information as well as the combination of dietary and plasma fatty acid data
336 which clearly showed the beneficial effects of a higher plasma LA. Limitations of the study include

the observational study design that is unable to reveal the causality of the relations. In this national food consumption survey (NANS), body composition measurements were collected by trained field workers with body fat assessed using a Tanita® body fat analyser rather than gold standard methods such as magnetic resonance imaging, computed tomography or DEXA scans. This was due to the practical simplicity of using Tanita® as part of a national food consumption survey. It has been reported that Tanita® is not associated with a clinically significant decrement in performance relative to traditional impedence devices [66] although it is recognized that this technique may slightly overestimate fat mass relative to DEXA [67] and MRI [68]. A further limitation of this study was the use of total plasma fatty acids rather than lipid fractions given that different associations have been reported between phospholipid and cholesterol esters [69]. Finally, we acknowledge that alterations in proportions of circulating fatty acids with age are well described, with reductions in erythrocyte concentrations of linoleic acid reported to be in the order of 2 percentage points per decade [70]. In our study, those in the lowest quartile of plasma LA were older than those in the highest quartile. Hence, it is possible that age-related influences on body fat accumulation and on metabolic health may have influenced outcome. However, we controlled for age in all relevant analysis to attempt mitigate any such risk.

In conclusion, our results showed that plasma LA was inversely associated with adiposity, followed by haplotype of FADS genes and dietary intakes. A higher plasma LA profile was related to a healthier phenotype and markers of metabolic health even when controlling for BMI and waist circumference. Future work is needed to better understand the mechanism of obesity modified plasma LA profile on human health.
