ABSTRACT

Background & Aims: Genome-wide association studies (GWAS) have identified more than 20 susceptibility loci for esophageal adenocarcinoma (EA) and Barrett’s esophagus (BE). However, variants in these loci account for a small fraction of cases of EA and BE. Genetic factors might interact with environmental factors to affect risk of EA and BE. We aimed to identify single nucleotide polymorphisms (SNPs) that may modify the associations of body mass index (BMI), smoking, and gastroesophageal reflux disease (GERD), with risks of EA and BE.

Methods: We collected data on single BMI measurements, smoking status, and symptoms of GERD from 2284 patients with EA, 3104 patients with BE, and 2182 healthy individuals (controls) participating in the Barrett’s and Esophageal Adenocarcinoma Consortium GWAS, the UK Barrett’s Esophagus Gene Study, and the UK Stomach and Oesophageal Cancer Study. We analyzed 993,501 SNPs in DNA samples of all study subjects. We used standard case–control logistic regression to test for gene-environment interactions.

Results: For EA, rs13429103 at chromosome 2p25.1, near the RNF144A-LOC339788 gene, showed a borderline significant interaction with smoking status ($P=2.18 \times 10^{-7}$). Ever smoking was associated with an almost 12-fold increase in risk of EA among individuals with rs13429103-AA genotype (odds ratio=11.82; 95% CI, 4.03–34.67). Three SNPs (rs12465911, rs2341926, rs13396805) at chromosome 2q23.3, near the RND3-RBM43 gene, interacted with GERD symptoms ($P=1.70 \times 10^{-7}$, $P=1.83 \times 10^{-7}$, and $P=3.58 \times 10^{-7}$, respectively) to affect risk of EA. For BE, rs491603 at chromosome 1p34.3, near the EIF2C3 gene, and rs11631094 at chromosome 15q14, at the SLC12A6 gene, interacted with BMI ($P=4.44 \times 10^{-7}$) and pack-years of smoking history ($P=2.82 \times 10^{-7}$), respectively.

Conclusion: The associations of BMI, smoking, and GERD symptoms with risks of EA and BE appear to vary with SNPs at chromosomes 1, 2, and 15. Validation of these suggestive interactions is warranted.

KEY WORDS: esophageal neoplasm; genetic variants; risk factors; esophagus
INTRODUCTION

Over the past four decades, the incidence of esophageal adenocarcinoma (EA) has increased markedly in many Western populations. Among white males in the United States the incidence has increased almost 10-fold,¹ and rates continue to rise by 2% per year.² EA is a highly fatal cancer with a median overall survival of <1 year following diagnosis.³ EAs typically arise on a background of a pre-malignant change in the lining of the esophagus known as Barrett’s esophagus (BE). Thus, proposals to prevent EA-associated morbidity and mortality have suggested focusing on identifying patients with BE and enrolling them in endoscopic surveillance programs, or on identifying and modifying risk factors for neoplastic progression.⁴-⁶

Epidemiologic studies have identified frequent or persistent symptoms of gastroesophageal reflux disease (GERD),⁷,⁸ obesity,⁹ and smoking¹⁰,¹¹ as the principal factors associated with increased risks of EA and BE. These three factors together comprise almost 80% of the attributable burden of EA.¹²,¹³ Genetic factors also influence risk of EA and BE. Recent genome-wide association studies (GWAS) and post-GWAS studies have identified more than 20 loci significantly associated with risks of EA and BE,¹⁴ however, these variants seem to explain only a limited proportion of the heritability of these diseases (estimated to be 25% for EA and 35% for BE).¹⁵ It is possible that environmental risk factors for EA and BE may interact with multiple genes through various biological pathways to contribute to disease susceptibility. Given the strength of associations with known risk factors for EA and BE (especially when compared with most other cancers), and potentially shared biological pathways (e.g., inflammation) underlying these risk factors,¹⁶ identifying gene-environment interactions may be more plausible in the setting of EA and BE. These gene-environment interactions may account for some of the missing
heritability of EA and BE. However, previous efforts to identify gene-environment interactions for EA and BE have predominantly been candidate-based and have involved only small numbers of single nucleotide polymorphisms (SNPs).

With the aim of identifying SNPs that may modify the associations of body mass index (BMI), smoking and GERD symptoms with risks of EA and BE, we used pooled questionnaire and genetic data from several studies to conduct a large scale genome-wide gene-environment interaction study of EA and BE.
METHODS

Study Population

We obtained data from 1,512 EA patients, 2,413 BE patients, and 2,185 controls of European ancestry from 14 epidemiologic studies conducted in Western Europe, Australia, and North America participating in the International Barrett’s and Esophageal Adenocarcinoma Consortium (BEACON; http://beacon.tlvnet.net/) GWAS. The design of the BEACON GWAS has been described in detail previously.\textsuperscript{20} Histological confirmation of EA and BE was carried out for all the participating studies. The pooled dataset also included an additional 1,003 EA patients and 882 BE patients from the United Kingdom (UK) Stomach and Oesophageal Cancer Study and the UK Barrett’s Esophagus Gene Study, respectively.\textsuperscript{20} The EA patients in the UK Stomach and Oesophageal Cancer Study had International Classification of Diseases coding of malignant neoplasm of the esophagus (C15) and pathological diagnosis of adenocarcinoma (M8140-8575). The BE patients were identified at endoscopy with confirmed histopathological diagnosis of intestinal metaplasia in the UK Barrett's Esophagus Gene Study. Each contributing study was performed under institutional review board approval and all participants gave informed consent.

SNP Genotyping

Genotyping of buffy coat or whole blood DNA from all participants was conducted using the Illumina Omni1M Quad platform, in accordance with standard quality control procedures.\textsuperscript{21} For quality control, genotyped SNPs were excluded based on call rate <95%, Hardy-Weinberg Equilibrium \( P \)-value over controls of \(<10^{-4}\), or minor allele frequency (MAF) \(<2\%\). After quality assurance and quality control, 993,501 SNPs were used for the current analysis. The analysis was
restricted to the subset of ethnically homogenous individuals of European ancestry (confirmed in GWAS samples using principal components analysis).20

Environmental (“Exposure”) Variables

Individual-level exposure data for each study participant were harmonized and merged into a single de-identified dataset. The data were checked for consistency and completeness and any apparent inconsistencies were followed-up with individual study investigators. Depending on the study, data from self-reported written questionnaires or in-person interviews were obtained at or near the time of cancer diagnosis for EA patients, at or near the time of BE diagnosis for BE patients, and at the time of recruitment for controls. BMI was calculated as weight divided by square of height (kg/m²). For the analysis we selected the weight from each participant that likely reflected usual adult weight (prior to, for example, any disease-related weight loss). For tobacco smoking, the exposure variables were smoking status (ever vs. never) and total cigarette smoking exposure among ever smokers (pack-years of smoking exposure). Ever cigarette smoking was defined as either low threshold exposure (≥100 cigarettes over their whole life) or by asking whether they had ever smoked regularly. Pack-years of smoking exposure was derived by dividing the average number of cigarettes smoked daily by 20 and multiplying by the total number of years smoked. GERD symptoms were defined as the presence of heartburn (i.e., a burning or aching pain behind the sternum) or acid reflux (i.e., a sour taste from acid, bile or other stomach contents rising up into the mouth). For analysis, we used the highest reported frequency for either GERD symptom. Participants were then categorized as recurrent vs. not recurrent based on a frequency of weekly or greater GERD symptoms for ‘recurrent’.7 A total of
425 participants with missing values for all three covariates (BMI, smoking history, and history of GERD symptoms) were excluded from the analysis.

**Statistical Analysis**

We used standard case-control logistic regression to test for gene-environment interactions. SNP genotypes were treated as continuous variables and coded as 0, 1, or 2 copies of the minor allele. Exposure variables were either continuous (BMI and pack-years of smoking exposure) or dichotomous (smoking status and GERD symptoms). We modeled the gene-environment interaction by the product of the SNP genotype and the exposure variable, adjusting for age, sex, the first four principal components to control for possible population stratification, and the main terms of the SNP and the exposure variable. We used model-robust standard errors as suggested in Voorman et al.\textsuperscript{22} to avoid inflated test statistics that can arise due to underestimation of variability in gene-environment GWAS. For SNPs from each of the top gene-environment interaction hits (i.e., main text, \(P\)-value for interaction <5.0\(\times\)10\(^{-7}\); supplementary material, \(P\)-value for interaction <1.0\(\times\)10\(^{-6}\)) we also performed stratified analyses by genotype to examine the modified association of the known risk factor for EA or BE within the specific genotypes. Analyses were conducted using R software (The R Foundation for Statistical Computing, Vienna, Austria), the GWASTools package,\textsuperscript{23} and Stata 13.0 (StataCorp LP, College Station, TX, USA).
RESULTS

The final study sample included 2,284 EA patients, 3,104 BE patients, and 2,182 controls. Characteristics of the study sample are shown in Table 1. On average, BMI was higher among EA (mean, 28.4 kg/m²) and BE (28.7 kg/m²) patients than controls (27.0 kg/m²). Similarly, EA and BE patients were more likely than controls to be ever smokers (74.8%, 64.8%, and 59.1%, respectively) and to report history of recurrent GERD symptoms (46.9%, 52.9%, and 19.4%, respectively).

Gene-environment interactions for EA

For EA, at borderline genome-wide significance, one SNP interacted with smoking status and three interacted with recurrent GERD symptoms ($P$ for interactions ranging from $3.58 \times 10^{-7}$ to $1.70 \times 10^{-7}$) (Table 2, Figure 1a and 1b). At chromosome 2p25.1, rs13429103 (effect allele frequency [EAF]=15.0%) showed interaction with smoking status ($RNF144A-LOC339788$, $P = 2.18 \times 10^{-7}$ for interaction). We also observed borderline statistically significant interactions between recurrent GERD symptoms and rs12465911 ($P = 1.70 \times 10^{-7}$ for interaction), rs2341926 ($P = 1.83 \times 10^{-7}$ for interaction) and rs13396805 ($P = 3.58 \times 10^{-7}$ for interaction) at chromosome 2q23.3 ($RND3-RBM43$). These three SNPs are in high linkage disequilibrium (all $r^2 > 0.9$) as indicated in Figure 1b. Additional suggestive gene-environment interactions for EA (where $P<1.0 \times 10^{-6}$ for interaction) are shown in Supplementary Table 1.

In analyses stratified by genotype (Table 3), compared to never smoking, ever smoking was associated with nearly a 12-fold higher risk of EA among individuals with rs13429103-AA genotype (odds ratio [OR]=11.82, 95% confidence interval [CI] 4.03-34.67). In contrast, among
individuals with rs13429103-GG genotype, ever smoking conferred only 1.6-fold higher risk of
EA (OR=1.59, 95% CI 1.36-1.85). Similarly, the risk for EA associated with recurrent GERD
symptoms was higher in individuals with rs12465911-AA genotype (OR=13.12, 95% CI 6.21-
27.73) than among individuals with rs12465911-GG genotype (OR=2.80, 95% CI 2.29-3.41).
Additional stratified analyses for risk of EA are shown in Table 3 and Supplementary Table 2.

**Gene-environment interactions for BE**

For BE, at chromosome 1p34.3, we observed an interaction between rs491603 (EAF=16.5%) and
BMI (EIF2C3-LOC100128093, $P = 4.44 \times 10^{-7}$ for interaction) (Table 2, Figure 1c). At
chromosome 15p14, rs11631094 (EAF=28.7%) showed interaction with pack-years of smoking
exposure (SLC12A6, $P = 2.82 \times 10^{-7}$ for interaction) (Table 2, Figure 1d). Additional suggestive
significant interactions (where $P<1.0 \times 10^{-6}$ for interaction) for BE with pack-years of smoking
exposure at chromosomes 12q23.1, 16p12.3, and 17q12 are presented in Supplementary Table 1.

Stratified analyses by genotype showed that the risk for BE associated with obesity (BMI $\geq 30$
kg/m$^2$) was elevated by over 200% among individuals with rs491603-AA genotype (vs. BMI
$<25$ kg/m$^2$, OR=3.30, 95% CI 1.90-5.73) but only by approximately 50% among individuals
with rs491603-GG genotype (vs. BMI $<25$ kg/m$^2$, OR=1.52, 95% CI 1.38-1.67). Additional
stratified analyses of gene-environment interactions for BE are shown in Table 3 and
Supplementary Table 2.

**Cross-examination of discovered gene-environment interactions**
For each SNP in Table 2 and Supplementary Table 1 that had a borderline significant genome-wide interaction in either EA or BE, we examined the equivalent gene-environment interaction in BE and EA, respectively (Supplementary Table 3). For all SNPs discovered in EA, we observed nominal levels of significance ($P$-value for interaction $<0.05$) and ORs in the same direction but somewhat attenuated in BE. For SNPs discovered in BE, only half had $P$-value for interaction $<0.05$ in EA, although all had similar ORs to those in BE. Although obesity and GERD are correlated, none of the SNPs with $P$-value for interaction $<1.0\times10^{-6}$ with GERD had comparable ORs or $P$-values when testing for interaction with obesity and similarly for the one obesity SNP when tested for GERD.
DISCUSSION

To our knowledge, this is the first genome-wide gene-environment interaction study of EA and its precursor, BE. Although no gene-environment interactions reached genome-wide significance (i.e., $P<5.0 \times 10^{-8}$ for interaction), several borderline significant interactions were indicated between SNPs and known risk factors for EA and BE – BMI, smoking and GERD symptoms.

A number of studies have pursued candidate-based gene-environment analyses of EA, and reported interactions between BMI, smoking or GERD symptoms and selected SNPs in genes related to detoxification, angiogenesis, DNA repair, apoptosis, and extracellular matrix degradation.24-31 This body of work helped to establish the notion that the level of disease risk associated with GERD symptoms, in particular, may vary according to inherited genetic variation. All of these studies, however, were conducted in small samples (<350 cases) and were not replicated in independent populations. While direct comparison of our own results and these past findings is complicated by less-than-complete overlap of genotyped SNPs between studies, we did not find evidence in support of interactions between BMI, smoking or GERD symptoms and any assessed variants in previously-implicated genes: *GSTM1, GSTT1, VEGF, MGMT, EGF, IL1B, PERP, PIK3CA, TNFRSF1A, CASP7, TP53BP1, BCL2, HIF1AN, PDGRFA, VEGFR1*, or *MMP1* (Supplementary Table 4). It remains possible that nominal evidence for some of these associations may not have survived stringent correction for multiple comparisons, and larger samples are needed for true signals to reach significance. Alternatively, previously reported interactions may simply reflect chance findings in small samples since they did not validate in our large study population.
This study has several strengths. First, the pooled dataset including relatively large numbers of cases and controls provided us with a rare opportunity to perform, in parallel, genome-wide gene-environment interaction analyses for EA and its precursor lesion, BE. Past candidate-based gene-environment interaction studies of EA have focused on small numbers of genes selected according to biological plausibility, and collectively these reports sampled only a small fraction of the total SNPs presently analyzed (N=993,501). Such preconceived “gene-centric” SNP selection methods fail to capture the large fraction of non-coding intergenic variations that have been linked to altered risk for these two conditions, and also artificially restricts the “genic” search space based on limited mechanistic knowledge, a limitation that is overcome by an unbiased comprehensive genome-wide gene-environment interaction assessment. Second, our study draws on genetic and epidemiologic data from a recent consortium-based GWAS of EA/BE,20 which is the largest of its kind. This sizable study sample afforded greater power to detect gene-environment interactions than in any previous study. Third, all genotyping from this GWAS was conducted on a single platform and in a single laboratory, and subjected to stringent quality control procedures. Most GWAS analyses test only an additive model since an additive model has reasonable power to detect both additive and dominant effects and the two models yield similar results and many GWAS analyses, including ours, are underpowered to detect recessive effects. Nevertheless, for completeness we also tested a dominant model for the 16 SNPs with P-value for interaction <1.0×10^-6 (Table 2 and Supplementary Table 1), and found slightly attenuated results of the ORs for some GxE interactions (data not shown).

Our study also has some limitations. First, our ability to detect true gene-environment interactions may have been limited by the manner in which the environmental (exposure)
variables were measured and harmonized. For example, recall bias is a possibility during retrospective reporting of the exposures in the parent case-control studies. However, respondents were unaware of their genotype status at the time of the interviews, mitigating the impact of any possible recall bias in our interaction analyses. Similarly, while considerable care was taken during data harmonization, as described in a series of recent pooled analyses,\textsuperscript{10, 11} some potential for measurement error of the exposures examined is possible. However, given case-control status was not considered during this process, any errors from harmonization would be non-differential, resulting in attenuation of the resulting ORs. Second, central obesity (e.g., waist-to-hip ratio) has been found to be more strongly associated with the risk of BE than BMI; however, as waist and hip measurements were not collected in the majority of the included studies we were unable to examine for interactions with central obesity. Third, despite the comprehensive nature of the genome-wide analysis, we were nonetheless limited to examining common genetic variation (MAF>2%) represented on the Illumina Omni1M Quad GWAS platform employed. Further large-scale studies based on whole-exome or whole-genome sequencing would be required to identify additional gene-environment interactions with rare variants, and more precisely map the reported associations. Finally, our study results should be considered as discovery findings, worthy of independent replication. None of the interactions studied reached genome-wide significance (i.e., \(P<5.0\times10^{-8}\) for interaction). This may be because there are truly no gene-environment interactions or it may be that power was still limited to detect modest or weak interactions despite our large sample size. In our analyses of 2,284 EA patients, 3,104 BE patients, and 2,182 controls, we were adequately powered to detect interactions with an interaction OR in the range of 1.98 to 2.52 for MAF in the observed range (0.11–0.43), assuming a main effect of 1.08 for log-additive SNPs, a main effect of 1.90 for binary risk factors, and an \(\alpha\)
of $5.0 \times 10^{-8}$. Given the large worldwide consortia sample of patients participating in this work, few additional studies of EA and BE patients are currently available and have data for replication, thus such work may require additional time for study patients to accrue.

In conclusion, our report describes the first genome-wide gene-environment interaction analysis for EA and BE. These findings provide evidence that the magnitude of disease risk associated with BMI, smoking, and GERD symptoms may differ according to germline genetics, and suggest the potential utility of combing epidemiologic exposure data with selected genotyping for comprehensive risk assessment in patients susceptible to EA/BE. Pending validation of the observed interactions in independent study populations, further analyses will be required to investigate the biological basis for differential disease risk associated with the risk factors investigated in the presence of these variants.
