Non-Orthogonal Multiple Access with Improper Gaussian Signaling

H. D. Tuan, A. A. Nasir, H. H. Nguyen, T. Q. Duong and H. V. Poor

Abstract—Improper Gaussian signaling (IGS) helps to improve the throughput of a wireless communication network by taking advantage of the additional degrees of freedom in signal processing at the transmitter. This paper exploits IGS in a general multiuser multi-cell network, which is subject to both intra-cell and inter-cell interference. With IGS under orthogonal multiple access (OMA) or non-orthogonal multiple access (NOMA), designs of transmit beamforming to maximize the users’ minimum throughput subject to transmit power constraints are addressed. Such designs are mathematically formulated as nonconvex optimization problems of structured matrix variables, which cannot be solved by popular techniques such as weighted minimum mean square error or convex relaxation. By exploiting the lowest computational complexity of $2 \times 2$ linear matrix inequalities, lower concave approximations are developed for throughput functions, which are the main ingredients for devising efficient algorithms for finding solution of these difficult optimization problems. Numerical results obtained under practical scenarios reveal that (i) there is an almost two-fold gain in the throughput by employing IGS instead of the conventional proper Gaussian signaling (PGS) under both OMA and NOMA; and (ii) NOMA-IGS offers better throughput compared to that achieved by OMA-IGS.

Index Terms—Transmission beamforming, improper Gaussian signaling (IGS), non-orthogonal multiple access (NOMA), multi-cell networks, nonconvex optimization, $2 \times 2$ linear matrix inequality

I. INTRODUCTION

The pressing need for wireless spectrum sharing among users offers the opportunities for applications of signal processing techniques at both transmit and receive ends to manage not only the background noise but also diversified interference sources such as intra-cell and inter-cell interference. Conventionally, communication systems use proper Gaussian signaling (PGS), under which transmit signals are proper Gaussian, so they are uncorrelated with their complex conjugates and their probability distribution is invariant under rotation in the complex plane. As such, they are fully characterized by their covariance matrix and can be generated from proper Gaussian information bearing sources by linear precoding. Using PGS thus simplifies the task of analyzing the performance of communication systems. Moreover, for Gaussian noise-limited channels such as single-user channels, conventional PGS is optimal [1].

In terms of sum-capacity, PGS is also optimal for multiple-input single-output (MISO) and multiple-input multiple-output (MIMO) broadcast channels by dirty-paper-coding (DPC) [2]–[5]. As clearly explained in [6], with DPC, there is one user who does not suffer any interference so the optimal transmit signal for this user is proper complex Gaussian as in the single-user case. The next user is interfered with the previous user only, whose signal is already proper complex Gaussian, so the optimal transmit signal of the next user is also proper complex Gaussian. The reasoning can be successively applied to all users. An important observation is that the optimality of PGS is strictly tied to DPC, which is not practical for more than two users.

In contrast to PGS, improper Gaussian signaling (IGS) relaxes the Gaussian properness to attain additional degrees of signaling freedom. The improperness of the transmit signals in IGS implies that they are correlated with their complex conjugates, making their pseudo-covariance matrix nonzero. As such, they must be generated from proper Gaussian information bearing sources by widely linear precoding. The superiority of IGS over PGS in terms of degree of freedom has been analyzed in single-input single-output (SISO) interference channel [7]–[13], MIMO interference channel [14]–[19], where there are multiple unicast transmitter-receiver pairs to share the spectrum medium over the same time. The achieved degree of freedom by IGS in broadcast communications has also been analysed...
in [15], [20].

As the joint design of IGS covariance and pseudo-covariance matrices in MISO broadcast channel is highly complex, [21] addressed their design separately by semi-definite relaxation (SDR), which is computationally inefficient as it involves matrix optimization of augmented dimensionality [22], [23]. In addition, since rank-one constraint is dropped, SDR may fail to find just a feasible point, especially, when there are many constraints or the objective function is non-smooth (such as a max-min function). The additional SDR-based randomization for locating a feasible point is both theoretically and practically inefficient [22].

On the other hand, non-orthogonal multiple access (NOMA) [24]–[26], which allows some users to access channels of other users in such a way that interference is reduced, is one of the promising strategies to accommodate more users in sharing spectrum as compared to the conventional orthogonal multiple access (OMA) [27], [28]. Naturally, PGS for OMA (PGS-OMA) and for NOMA (PGS-NOMA) have been comprehensively studied in multi-cell broadcast interference networks (see e.g. [23], [29]–[32] and references therein). In particular, based on a nonsmooth (non-differentiable) function optimization model proposed firstly in [29], references [31], [32] show that the design problem of PGS-NOMA is not more computationally difficult than that of PGS-OMA. In fact, both problems can be efficiently solved by path-following computational procedures, which are based on the same nonconcave function approximation framework.

Against the above background, the present paper aims to lay down the nonconvex optimization foundation for designing IGS for both OMA (OMA-IGS) and NOMA (NOMA-IGS) in a general multi-cell broadcast communication network, where the multi-antenna base station (BS) in each cell serves multiple single-antenna users. To the authors’ best knowledge, this is the first paper to consider NOMA-IGS. The problem of designing IGS is fundamentally different from that of PGS because the latter is based on logarithmic function optimization in beamforming vectors while the former is based on log-determinant functions in IGS beamforming vectors. Accordingly, we propose path-following algorithms allowing us to simulate and analyze the performance of OMA-IGS and NOMA-IGS under both single-cell and multi-cell setups. The rigorously-conducted tests by varying different sets of simulation parameters, e.g., number of BS antennas, number of users, BS transmit power, or noise power reveal that there is almost two-fold gain in the throughput by employing IGS instead of PGS under both NOMA and OMA systems. Furthermore, with IGS, NOMA offers better throughput compared to that achieved by OMA.

The rest of the paper is organized as follows. Section II is devoted to studying OMA-IGS. In particular, a new lower concave approximation for the log-determinant function of improper Gaussian signaling throughput is developed in this section. Section III is devoted to the study of NOMA-IGS, which makes use of the function approximation developed in Section II. Section IV provides comprehensive numerical results to substantiate the theoretical results established in Sections II and III. Finally, Section V concludes the paper.

Notation. Bold-faced upper-case letters, e.g., \( \mathbf{X} \) are used for matrices, bold-faced lower-case letters, e.g., \( \mathbf{x} \) are used for vectors, and normal lower-case letters, e.g., \( x \), are used for scalars. \( \mathbf{I}_n \) is the identity matrix of size \( n \times n \). \( \mathbf{X}^H \), \( \mathbf{X}^T \), and \( \mathbf{X}^* \) are the Hermitian transpose, normal transpose, and conjugate of the matrix \( \mathbf{X} \), respectively. The inner product \( \langle \mathbf{X}, \mathbf{Y} \rangle \) of the matrices \( \mathbf{X} \) and \( \mathbf{Y} \) is defined as \( \text{trace}(\mathbf{X}^H \mathbf{Y}) \). Denote by \( (\mathbf{X}) \) the trace of the matrix \( \mathbf{X} \), and by \( \lVert \mathbf{X} \rVert \) its determinant. \( \| \cdot \| \) stands for matrix’s Frobenius norm or vector’s Euclidean norm. \( \mathbb{C} \) is the set of all complex numbers and \( \mathbb{R} \) is the set of all

\[
2 \times 2 \text{ LMI} \begin{bmatrix} x_1 & x_2 \\ x_3 & x_3 \end{bmatrix} \succeq 0 \text{ is seen as the set of convex quadratic constraints } x_1 \geq 0, x_3 \geq 0, \text{ and } x_1x_3 - (x_2)^2 \geq 0.
\]

\(^1\)The degree of freedom is an appropriate metric only under very high signal-to-noise ratios.
real numbers. $x \sim \mathcal{CN}(\eta, Z)$ means that $x$ is a complex random vector following a circular Gaussian distribution with mean $\eta$ and covariance matrix $Z$. $\nabla f(x)$ is the gradient of function $f(\cdot)$ with respect to its variable $x$. $A \succ 0$ means that the matrix $A$ is positive definite. $\mathbb{E}\{\cdot\}$ denotes the expectation operator. $[X]^2 = XX^\dagger$ for real valued matrix $X$. Row$(a_i)_{i \in I}$ arranges $a_i$, $i \in I$ in row-block. For instance Row$(a_i)_{i \in \{1,2\}} = [a_1 \ a_2]$.

II. IGS FOR ORTHOGONAL MULTIPLE ACCESS (OMA)

Consider the downlink of a multi-user multi-cell wireless communication system which consists of $K$ cells, where the BS of each cell is equipped with $N_t$ antennas to serve $N$ single-antenna users (also called user equipments, or UEs) within its cell. In each cell, there are $\frac{N}{K}$ cell-centered UEs, which are located close to the BS and $\frac{N}{K}$ cell-edge UEs, which are located far away from the BS and near the cell boundary. The $\frac{N}{K}$ far UEs in each cell not only experience poorer channel conditions than other $\frac{N}{K}$ near UEs, but also suffer more severe inter-cell interference from adjacent cells. Of course the case $K = 1$ corresponds to the single-cell setup, which will also be considered in Section IV together with the case of multi-cell setup $K > 1$. In this work, we assume the availability of full channel state information at the BSs and focus on the resource allocation problem. In a single-cell setup, channel information can be obtained by uplink channel estimation via the principle of time division duplexing and channel reciprocity. In a multi-cell setup, channel state information can be acquired by different means, e.g., through coordination among BSs [37].

Let $K \triangleq \{1, 2, \ldots, K\}$ and $N \triangleq \{1, 2, \ldots, N\}$, where $N$ is an even integer. The $n$-th UE in the $k$-th cell is referred to as UE $(k, n) \in \mathcal{M} \triangleq K \times N$. The cell-centered UEs are UE $(k, n)$, $n \in \mathcal{N}_c \triangleq \{1, 2, \ldots, \frac{N}{2}\}$ while the cell-edge UEs are UE $(k, n)$, $n \in \mathcal{N}_e \triangleq \{\frac{N}{2} + 1, \ldots, N\}$. Thus the set of cell-centered UEs and the set of cell-edge UEs are $\mathcal{M}_c \triangleq K \times \mathcal{N}_c$ and $\mathcal{M}_e \triangleq K \times \mathcal{N}_e$, respectively.

Let $x_{k',n'}$ be the signal that BS $k'$ intends to transmit to its UE $(k', n')$. Then the transmitted signal of BS $k'$ is $\sum_{n'=1}^{N} x_{k',n'}$. The received signal at UE $(k, n)$ is given by

$$y_{k,n} = \sum_{(k',n') \in \mathcal{M}} h_{k',k,n} x_{k',n'} + n_{k,n},$$

where $h_{k',k,n} \in \mathbb{C}^{1 \times N_t}$ is the MISO channel from BS $k'$ to UE $(k, n)$, and $n_{k,n} \sim \mathcal{CN}(0, \sigma^2)$ is the background noise.

Let the message intended for UE $(k', n')$ be $s_{k',n'} \sim \mathcal{CN}(0, 1)$. This message is processed by a widely linear precoder to produce the following IGS message for transmission:

$$x_{k',n'} = w_{1,k',n'} s_{k',n'} + w_{2,k',n'} s_{k',n'}^*,$$

where $w_{1,k',n'} \in \mathbb{C}^{N_t \times 1}$ and $w_{2,k',n'} \in \mathbb{C}^{N_t \times 1}$. Then, the received signal in (1) at UE $(k, n)$ is rewritten as

$$y_{k,n} = \sum_{(k',n') \in \mathcal{M}} h_{k',k,n} (w_{1,k',n'} s_{k',n'} + w_{2,k',n'} s_{k',n'}^*) + n_{k,n}.\quad (3)$$

In what follows we use the following notations:

$$w_{k,n} \triangleq \{R\{w_{1,k,n}\}, R\{w_{2,k,n}\}, i = 1, 2\} \in \mathbb{R}^{4N_t},$$

$$\bar{H}_{k',k,n} \triangleq \begin{bmatrix} R\{h_{k',k,n}\} & -3 R\{h_{k',k,n}\} \\ 3 R\{h_{k',k,n}\} & R\{h_{k',k,n}\} \end{bmatrix} \in \mathbb{R}^{2 \times (2N_t)},$$

and

$$\bar{y}_{k,n} \triangleq \begin{bmatrix} R\{y_{k,n}\} \\ 3 R\{y_{k,n}\} \end{bmatrix} \in \mathbb{R}^2, \bar{s}_{k,n} \triangleq \begin{bmatrix} R\{s_{k,n}\} \\ 3 R\{s_{k,n}\} \end{bmatrix} \in \mathbb{R}^2,$$

$$\bar{n}_{k,n} \triangleq \begin{bmatrix} n_{k,n} \\ 3 n_{k,n} \end{bmatrix} \in \mathbb{R}^2. \quad (5)$$

Also, define a linear mapping from $\mathbb{R}^{4N_t}$ to $\mathbb{R}^{(2N_t) \times 2}$,

$$L(w_{k,n}) = \begin{bmatrix} R\{w_{1,k,n}\} + R\{w_{2,k,n}\} \\ 3 R\{w_{1,k,n}\} - 3 R\{w_{2,k,n}\} \\ 3 R\{w_{1,k,n}\} + 3 R\{w_{2,k,n}\} \\ R\{w_{1,k,n}\} - R\{w_{2,k,n}\} \end{bmatrix} \in \mathbb{R}^{(2N_t) \times 2}.$$

Then Equation (3) can be rewritten as

$$\bar{y}_{k,n} = \sum_{(k',n') \in \mathcal{M}} \bar{H}_{k',k,n} L(w_{k',n'}) \bar{s}_{k',n'} + \bar{n}_{k,n}. \quad (6)$$

It is simple to verify that

$$\mathbb{E}\{[\bar{s}_{k',n'}]^2\} = \frac{1}{2} I_2, \mathbb{E}\{[\bar{n}_{k,n}]^2\} = \frac{1}{2} \sigma^2 I_2, \quad (7)$$

and

$$\mathbb{E}\{[\bar{H}_{k',k,n} L(w_{k',n'})]^2\bar{s}_{k',n'}^2\} = \frac{1}{2} [H_{k',k,n} L(w_{k',n'})]^2. \quad (8)$$

Thus, the throughput at UE $(k, n)$ in nats/sec/Hz is given by [1]

$$\rho_{k,n}(w) = \frac{1}{2} \ln \left| I_2 + \mathbb{E}\{[\bar{H}_{k,k,n} L(w_{k,n}) \bar{s}_{k,n}]^2\} \sum_{(k',n') \in \mathcal{M}\setminus\{(k,n)\}} \mathbb{E}\{[\bar{H}_{k',k,n} L(w_{k',n'}) \bar{s}_{k',n'}]^2\}^{-1} \right| - \frac{1}{2} \ln \left| I_2 + [H_{k,k,n} L(w_{k,n})]^2 \left( |\Lambda_{k,n}(w)|^2 + \sigma^2 I_2 \right)^{-1} \right|,$$

where

$$\Lambda_{k,n}(w) \triangleq \text{Row}[H_{k,k,n} L(w_{k,n})]_{(k',n') \in \mathcal{M}\setminus\{(k,n)\}}, \quad \text{and}$$

$$\hat{\Lambda}_{k,n}(w) \triangleq \text{Row}[H_{k',k,n} L(w_{k',n'})]_{(k',n') \in \mathcal{M}}. \quad (10)$$
By maximizing the worst user throughput, the max-min throughput criterion ensures fairness among all users. Such a performance criterion is very common in the literature and also adopted in this paper. The max-min throughput optimization problem is formulated as:

\[
\begin{align*}
\max_{\mathbf{w}} \quad & \psi(\mathbf{w}) \triangleq \min_{(k,n) \in \mathcal{M}} \rho_{k,n}(\mathbf{w}) \quad (12a) \\
\text{s.t.} \quad & \sum_{(k,n) \in \mathcal{M}} ||\mathbf{w}_{k,n}||^2 \leq \rho_{\max}^{(k,n)}, \quad k \in \mathcal{K}. \quad (12b)
\end{align*}
\]

The objective function (12a) is not only nonconcave but also nonsmooth, making (12) very computationally difficult. Moreover, the presence of linear mappings \( \mathcal{L}(\mathbf{w}_{k,n}) \) and \( \Lambda_{k,n}(\mathbf{w}) \) in the definition (9) for the throughput function \( \rho_{k,n} \) makes (12) complex structured, preventing application of the popular weighted minimum mean square error (WMMSE)-based approach [38]. This is also true even for the easier problems of smooth optimization such as the following sum throughput optimization problem

\[
\max_{\mathbf{w}} \quad \sum_{(k,n) \in \mathcal{M}} \rho_{k,n}(\mathbf{w}) \quad \text{s.t.} \quad (12b). \quad (13)
\]

On the other hand, using Shur’s complement to expand the determinant of \( 2 \times 2 \) matrix in (9) as done in [21] results in even much more complex forms of the throughput functions.

Fortunately, it has been recently shown in [30], [31] that many partial convex structures of throughput functions like the function \( \rho_{k,n} \) in (12) can be systematically exploited for tractable computation. Specifically, by observing that \( \rho_{k,n} \) in (12) is composed of a nonlinear function \( f \) defined by

\[
\begin{align*}
f(\mathbf{X}_1, \mathbf{X}_2) &= \ln |\mathbf{I}_2 + [\mathbf{X}_1]^2 ([\mathbf{X}_2]^2 + \sigma^2 \mathbf{I}_2)^{-1}| \quad (14)
\end{align*}
\]

and linear mappings \( \mathbf{X}_1(\mathbf{w}) \triangleq \mathbf{H}_{k,n} \mathcal{L}(\mathbf{w}_{k,n}) \) and \( \mathbf{X}_2(\mathbf{w}) = \Lambda_{k,n}(\mathbf{w}) \), i.e.,

\[
(15)
\]

one can simply approximate \( \rho_{k,n}(\mathbf{w}) \) by approximating the function \( f(\mathbf{X}_1, \mathbf{X}_2) \). Indeed, if \( \mathbf{X}_1(\mathbf{w}), \mathbf{X}_2(\mathbf{w}) \) is a convex/concave approximation of \( f(\mathbf{X}_1, \mathbf{X}_2) \) then the composed function \( f(\mathbf{X}_1(\mathbf{w}), \mathbf{X}_2(\mathbf{w})) \) is also a convex/concave approximation of \( \rho_{k,n}(\mathbf{w}) \) because such partial convex structures are preserved under linear mappings \( \mathbf{X}_1(\mathbf{w}) \) and \( \mathbf{X}_2(\mathbf{w}) \) [39]. The key ingredient is the following result, whose proof given in the Appendix.

**Lemma 1:** For all matrices \( \mathbf{X}_i \in \mathbb{R}^{2 \times 2} \) and \( \bar{\mathbf{X}}_i \in \mathbb{R}^{2 \times 2} \), \( i = 1, 2 \), the following inequality holds true

\[
f(\mathbf{X}_1, \mathbf{X}_2) \geq f(\bar{\mathbf{X}}_1, \bar{\mathbf{X}}_2) + 4 - \sigma^2 \left( [\bar{\mathbf{X}}_2]^2 + \sigma^2 \mathbf{I}_2 \right)^{-1}
\]

\[
- \left( \sum_{i=1}^{2} \bar{\mathbf{X}}_i^2 + \sigma^2 \mathbf{I}_2, \left( \sum_{i=1}^{2} \bar{\mathbf{X}}_i \bar{\mathbf{X}}_i^T + \mathbf{X}_i \bar{\mathbf{X}}_i^T \right)^{-1} \right)
\]

\[
- \left( [\bar{\mathbf{X}}_i]^2 + \sigma^2 \mathbf{I}_2 \right)^{-1}, \quad (15)
\]

over the convex trust region constrained by the 2 x 2 LMI

\[
\sum_{i=1}^{2} (\mathbf{X}_i \mathbf{X}_i^T + \mathbf{X}_i \bar{\mathbf{X}}_i^T - [\mathbf{X}_i]^2) \succeq 0. \quad (16)
\]

The right hand side (RHS) of (15) is a concave function of \((\mathbf{X}_1, \mathbf{X}_2),^3 \) which matches with \( f \) at \((\mathbf{X}_1, \mathbf{X}_2) \).

It is pointed out that the following inequality was obtained in [30], [31]:

\[
f(\mathbf{X}_1, \mathbf{X}_2) \geq f(\mathbf{X}_1, \mathbf{X}_2) + \sigma^2 \langle \mathbf{B} \rangle > 0, \quad (17)
\]

with \( a = f(\mathbf{X}_1, \mathbf{X}_2) - \langle \mathbf{X}_1 \rangle^2 - \langle \mathbf{X}_2 \rangle^2 \), \( \mathbf{A} = \langle \mathbf{X}_1 \rangle^2 + \sigma^2 \mathbf{I}_2 \), and \( 0 \leq \mathbf{B} = \langle \mathbf{X}_2 \rangle^2 + \sigma^2 \mathbf{I}_2 \). The RHS of (17) is thus a sum of two uncorrelated concave quadratic functions \( f_i(X_i) \) of the trust region (18) for the variable \( X_1 \) only. In contrast, the variables \( X_1 \) and \( X_2 \) are correlated in the RHS of (15) over the trust region (16) involving both of them. This makes the RHS of (15) more refined than the RHS of (18) for approximating the function \( f \).

Let \( \mathbf{w}^{(\kappa)} \triangleq \{ \mathbf{w}_{k,n}^{(\kappa)}, (k, n) \in \mathcal{M} \} \) be a feasible point for (12) that is found at the \((\kappa-1)\)th iteration. With regard to the function \( \rho_{k,n}(\mathbf{w}) \) in (12a), applying the inequality (15) for

\[
\begin{align*}
\mathbf{X}_1 &= \mathbf{H}_{k,n} \mathcal{L}(\mathbf{w}_{k,n}), \quad \mathbf{X}_2 = \Lambda_{k,n}(\mathbf{w}), \quad \text{and} \\
\bar{\mathbf{X}}_1 &= \mathbf{H}_{k,n} \mathbf{w}_{k,n}, \quad \bar{\mathbf{X}}_2 = \Lambda_{k,n}(\mathbf{w}^{(\kappa)}),
\end{align*}
\]

yields the following lower concave approximation:

\[
\begin{align*}
\rho_{k,n}^{(\kappa)}(\mathbf{w}) &\geq \frac{1}{2} \left( a^{(\kappa)} - \left( \Lambda_{k,n}(\mathbf{w}) \Lambda_{k,n}^T(\mathbf{w}^{(\kappa)}) \right) + \Lambda_{k,n}(\mathbf{w}) \Lambda_{k,n}^T(\mathbf{w}) \right)
\end{align*}
\]

\[
\text{over the trust region}
\]

\[
\Lambda_{k,n}(\mathbf{w}) \Lambda_{k,n}^T(\mathbf{w}) \succeq 0, \quad (20)
\]

\[
(k, n) \in \mathcal{M},
\]

\[
(\mathbf{A}, \mathbf{X}^{-1}) \text{ with } \mathbf{A} \succeq 0 \text{ is convex in } \mathbf{X} \succ 0 \text{ (see e.g. [40, p. 467] or [41, Appendix A]) so the second term in the RHS of (15) is a convex function, while the third term in the RHS of (15) is obviously a concave quadratic function.}
\]
the definition (19). Algorithm 1 thus generates a sequence \( \rho \) where the last equality follows from the equality simulation results in [23] show that this type of solution is optimality condition. It is noteworthy to point out that the of (12), which satisfies the Karush-Kuh-Tucker (KKT)

\[
\Psi_{k,n}(w^{(\kappa+1)}) > \Psi_{k,n}(w^{(\kappa)})
\]

because \( w^{(\kappa+1)} \) is the optimal solution of (22) while \( w^{(\kappa)} \) is its feasible point. Therefore,

\[
\Psi(w^{(\kappa+1)}) = \Psi(w^{(\kappa+1)}) > \Psi_{k,n}(w^{(\kappa)}) > \Psi(w^{(\kappa)})
\]

where the last equality follows from the equality \( \rho_{k,n}(w^{(\kappa)}) = \rho_{k,n}(w^{(\kappa)}) \), which is easily checked using the definition (19). Algorithm 1 thus generates a sequence \( \{w^{(\kappa)}\} \) of improved feasible points for (12). Using similar arguments as in [23], it can be easily shown that Algorithm 1 at least converges to a locally optimal solution of (12), which satisfies the Karush-Kuh-Tucker (KKT) optimality condition. It is noteworthy to point out that the simulation results in [23] show that this type of solution is often globally optimal.

### Algorithm 1 OMA-IGS Max-min Rate Optimization Algorithm

**Initialization:** Set \( \kappa := 0 \) and a feasible point \( w^{(0)} \) satisfying the power constraint (12b).

1: \textbf{repeat}
2: \hspace{1em} Solve the convex optimization problem (22) to obtain the optimal solution \( w^{(\kappa+1)} \).
3: \hspace{1em} Set \( \kappa := \kappa + 1 \).
4: \textbf{until} Convergence of the objective in (12).

where

\[
a_{k,n}^{(\kappa)} \triangleq 2 \rho_{k,n}(w^{(\kappa)}) + 4 - \sigma^2 \left( \frac{1}{2} (A_{k,n}^{(\kappa)})^2 + \sigma^2 I_2 \right)^{-1}, \quad (21a)
\]

\[
0 < A_{k,n}^{(\kappa)} \triangleq [A_{k,n}(w^{(\kappa)})]^2 + \sigma^2 I_2, \quad (21b)
\]

\[
0 < B_{k,n}^{(\kappa)} \triangleq [A_{k,n}(w^{(\kappa)})]^2 + \sigma^2 I_2^{-1}. \quad (21c)
\]

Thus, at the \( \kappa \)-th iteration, we solve the following convex optimization problem to generate the next iterative feasible point \( w^{(\kappa+1)} \) for (12):

\[
\max_w \Psi^{(\kappa)}(w) \triangleq \min_{(k,n) \in M} \rho_{k,n}(w) \quad \text{s.t.} \quad (12b),(20). \quad (22)
\]

This problem involves \( 2KNN_t \) decision variables and \( K \) quadratic constraints in (12b) of power constraint plus \( KN \times 2 \times 2 \) LMI constraints (20) of trust region, so its computational complexity is \( \mathcal{O}((2KNN_t)^3 (KN + K)) \) [36, p. 4].

Algorithm 1 outlines the steps to solve the the max-min rate problem (12). Note that

\[
= \Psi(w^{(\kappa+1)}) > \Psi(w^{(\kappa)}) \quad (23)
\]

Before closing this section, let us mention that the following problem of sum throughput maximization subject to quality-of-service (QoS) constraints

\[
\max_w \sum_{(k,n) \in M} \rho_{k,n}(w) \quad \text{s.t.} \quad (12b),
\]

\[
\rho_{k,n}(w) \geq \gamma_{k,n}, (k,n) \in M
\]

can be addressed similarly, where its next iterative feasible point \( w^{(\kappa+1)} \) is generated as the optimal solution of the convex optimization problem

\[
\max_w \sum_{(k,n) \in M} \rho_{k,n}(w) \quad \text{s.t.} \quad (12b),
\]

\[
\rho_{k,n}(w) \geq \gamma_{k,n}, (k,n) \in M. \quad (25)
\]

Compared to the problem of sum throughput maximization (13), the problem (25) is much more meaningful as it enables the network to serve all its users by setting the QoS constraints in terms of users’ throughput in (25). Without these QoS constraints, the network will concentrate its throughput at a few users of the best channel condition, offering almost zero throughput to other users.

### III. IGS for Non-orthogonal Multiple Access (NOMA)

With NOMA, by exploiting the large difference in the channel conditions between the cell-centered and cell-edge UEs, each cell-centered UE \((k,n) \in \mathcal{N}_c\) is randomly paired with cell-edge UE \((k,p(n)) \in \mathcal{N}_e\) of the same cell to create a virtual cluster. This paring operation in NOMA would improve the network throughput. For notational convenience, the paired UE \((k,p(n))\) for UE \((k,n)\) is chosen, such that \(p(n) = n + \frac{N}{2} \).

The signal received by cell-centered UE \((k,n) \in \mathcal{M}_c\) is given by the same expression (3), while the signal received by cell-edge UE \((k,p(n)) \in \mathcal{M}_e\) can be expressed as

\[
y_{k,p(n)} = \sum_{(k',n') \in \mathcal{M}} h_{k',k,p(n)}(w_{1,k',n',s_{k',n'}} + w_{2,k',n',s_{k',n'}} + n_{k,p(n)}, \quad (26)
\]

which is rewritten similarly to (6) as

\[
y_{k,p(n)} = \sum_{(k',n') \in \mathcal{M}} \bar{H}_{k',k,p(n)}(w_{k',n'}) + n_{k,p(n)}, \quad (27)
\]

In NOMA, the information \( s_{k,p(n)} \) is first decoded by both the cell-centered UE \((k,n)\) and the cell-edge UE \((k,p(n))\). As such the throughput of UE \((k,p(n))\) is given by the minimum of the two throughput expressions, i.e.,

\[
\tilde{\rho}_{k,p(n)}(w) = \min\{\rho_{k,p(n)}^{(1)}(w), \rho_{k,p(n)}^{(2)}(w)\}. \quad (28)
\]
In particular, the term $\hat{\rho}_{k,p(n)}^{(1)}(w)$ in (28) is the throughput at UE $(k,n)$, when trying to decode $s_{k,p(n)}$:

$$\hat{\rho}_{k,p(n)}^{(1)}(w) = \frac{1}{2} \ln \left[ 1 + \frac{[H_{k,k,n}(w,k,p(n))^2]}{[\mathbf{I}_2 + H_{k,k,n}(w,k,p(n))]^2} \right] \times \left[ (\gamma_{k,p(n)}^{(1)}(w))^2 + \sigma^2 \mathbf{I}_2 \right]^{-1}, \quad (29)$$

with

$$\gamma_{k,p(n)}^{(1)}(w) \triangleq \text{Row}([H_{k,k,n}(w,k,p(n))]_{(k',n') \in M \setminus \{(k,p(n))\}}).$$

Likewise, $\hat{\rho}_{k,p(n)}^{(2)}(w)$ is the throughput at UE $(k,p(n))$, when trying to decode its own information $s_{k,p(n)}$:

$$\hat{\rho}_{k,p(n)}^{(2)}(w) = \frac{1}{2} \ln \left[ 1 + \frac{[H_{k,k,n}(w,k,p(n))^2]}{[\mathbf{I}_2 + H_{k,k,n}(w,k,p(n))]^2} \right] \times \left[ (\gamma_{k,p(n)}^{(2)}(w))^2 + \sigma^2 \mathbf{I}_2 \right]^{-1}, \quad (31)$$

with

$$\gamma_{k,p(n)}^{(2)}(w) \triangleq \text{Row}([H_{k,k,p(n)}(w,k',n')]_{(k',n') \in M \setminus \{(k,p(n))\}}).$$

The decoding in NOMA is such that UE $(k,n) \in M_c$ first decodes the message $s_{k,p(n)}$ and then removes it from the superimposed received signal in order to decode its own information $s_{k,n}$. Thus, the throughput for decoding $s_{k,n}$ by UE $(k,n)$ is given by

$$\hat{\rho}_{k,n}(w) = \frac{1}{2} \ln \left[ 1 + \frac{[H_{k,k,n}(w,k,n)]^2}{[\mathbf{I}_2 + H_{k,k,n}(w,k,n)]} \right] \times \left[ (\gamma_{k,n}(w))^2 + \sigma^2 \mathbf{I}_2 \right]^{-1}, \quad (33)$$

for

$$\gamma_{k,n}(w) \triangleq \text{Row}([H_{k,k,n}(w,k',n')]_{(k',n') \in M \setminus \{(k,n),(k,p(n))\}}).$$

The users’ max-min throughput is defined by

$$\min_{(k,n) \in M_c} \min \{\hat{\rho}_{k,n}(w), \hat{\rho}_{k,p(n)}(w)\} = \min_{(k,n) \in M_c} \min \{\hat{\rho}_{k,n}(w), \min \{\hat{\rho}_{k,p(n)}^{(1)}(w), \hat{\rho}_{k,p(n)}^{(2)}(w)\}\}. \quad (35)$$

The max-min throughput optimization problem is then formulated as:

$$\max_w \Phi(w) \triangleq \min_{(k,n) \in M_c} \min \{\hat{\rho}_{k,n}(w), \hat{\rho}_{k,p(n)}^{(1)}(w), \hat{\rho}_{k,p(n)}^{(2)}(w)\} \quad \text{s.t.} \quad (12b). \quad (36)$$

Since the objective function in (36) is non-concave, in what follows, we first find the lower bound concave approximations for $\hat{\rho}_{k,n}(w)$, $\hat{\rho}_{k,p(n)}^{(1)}(w)$, and $\hat{\rho}_{k,p(n)}^{(2)}(w)$. Let $w^{(s)}$ be a feasible point for (36) that is found at the $(k-1)$th iteration. Similarly to (19),

$$\hat{\rho}_{k,n}(w) \geq \hat{\rho}_{k,n}^{(s)}(w) \triangleq \frac{1}{2} \hat{\rho}_{k,n}^{(s)}(w) + 4 - \sigma^2 \left( [\gamma_{k,n}(w)]^2 + \sigma^2 \mathbf{I}_2 \right)^{-1}. \quad (37)$$

over the trust region

$$\hat{\gamma}_{k,n}(w) \triangleq \left( \hat{\gamma}_{k,n}(w^{(s)}) \right)^T + \hat{\gamma}_{k,n}(w^{(s)}) + \left( \hat{\gamma}_{k,n}(w^{(s)}) \right)^T \hat{\gamma}_{k,n}(w^{(s)}) \geq 0, \quad (38)$$

with

$$\hat{\gamma}_{k,n}(w) \triangleq \left[ H_{k,k,n}(w,k',n') \right]_{(k',n') \in M \setminus \{(k,p(n))\}}. \quad (39a)$$

Furthermore,

$$\hat{\rho}_{k,n}^{(1)}(w) \geq \hat{\rho}_{k,n}^{(1)}(w) \triangleq \frac{1}{2} \hat{\rho}_{k,n}^{(1)}(w) + 4 - \sigma^2 \left( [\gamma_{k,n}(w)]^2 + \sigma^2 \mathbf{I}_2 \right)^{-1}. \quad (40)$$

over the trust region

$$\hat{\gamma}_{k,n}(w) \triangleq \left( \hat{\gamma}_{k,n}(w^{(s)}) \right)^T + \hat{\gamma}_{k,n}(w^{(s)}) + \left( \hat{\gamma}_{k,n}(w^{(s)}) \right)^T \hat{\gamma}_{k,n}(w^{(s)}) \geq 0, \quad (41)$$

with

$$\hat{\gamma}_{k,n}(w) \triangleq \left[ H_{k,k,n}(w,k',n') \right]_{(k',n') \in M \setminus \{(k,p(n))\}}. \quad (42a)$$

$$\hat{\rho}_{k,n}^{(1)}(w) \geq \hat{\rho}_{k,n}^{(1)}(w) \triangleq \frac{1}{2} \hat{\rho}_{k,n}^{(1)}(w) + 4 - \sigma^2 \left( [\gamma_{k,n}(w)]^2 + \sigma^2 \mathbf{I}_2 \right)^{-1}. \quad (42b)$$

$$0 < A_{k,n}^{(s)} \triangleq \left[ \gamma_{k,n}(w^{(s)}) \right]_2^2 + \sigma^2 \mathbf{I}_2, \quad (42c)$$

$$0 < B_{k,n}^{(s)} \triangleq \left[ \gamma_{k,n}(w^{(s)}) \right]_2^2 + \sigma^2 \mathbf{I}_2. \quad (42d)$$
Likewise, \[ \dot{\rho}_{k,p,n}^{(2)}(w) \geq \dot{\rho}_{k,p,n}^{(1)}(w) \]

\[
\frac{1}{2} \left( q_{k,p,n}^{(2)} - \left( \dot{\rho}_{k,p,n}^{(2)}(w) \right) \left( \dot{\rho}_{k,p,n}^{(1)}(w) \right)^T + \dot{\mu}_{k,p,n}^{(2)}(w) \right) - \left( \dot{\mu}_{k,p,n}^{(1)}(w) \right)^T - \left( \dot{\mu}_{k,p,n}^{(2)}(w) \right)^2 + \sigma^2 I_2 \right) \supseteq 0, (43)
\]

over the trust region

\[
\dot{\mu}_{k,p,n}^{(2)}(w) \Delta \left[ h_{k', k,p,n} C(w_{k', n'}) \right]_{(k', n') \in \mathcal{M}}, (45a)
\]

\[
q_{k,p,n}^{(2)}(w) \Delta 2 \dot{\mu}_{k,p,n}^{(1)}(w), (45b)
\]

\[
0 \sim \dot{\mu}_{k,p,n}^{(2)}(w) \Delta \left( \dot{\mu}_{k,p,n}^{(1)}(w) \right)^2 + \sigma^2 I_2, (45c)
\]

\[
0 \sim \dot{\mu}_{k,p,n}^{(2)}(w) \Delta \left( \dot{\mu}_{k,p,n}^{(1)}(w) \right)^2 + \sigma^2 I_2. (45d)
\]

Thus, at the \( \kappa \)-th iteration, we solve the following convex optimization problem to generate the next iterative feasible \( w^{(\kappa+1)} \) for (36)

\[
\max_w \Phi(w^{(\kappa+1)}) \Delta \min_{(k,n) \in \mathcal{M}} \left\{ \rho_{k,n}(w), \dot{\rho}_{k,p,n}(w) \right\}
\]

\[
\text{s.t. } (12b), (38), (41), (44). (46)
\]

Compared to OMA-IGS iteration (22), this NOMA-IGS iteration involves the same number \( 2KNN_t \) of decision variables but more \( KN/2 \times 2 \) LMI constraints (44), so its computational complexity is \( O((2KNN_t)^3 (1.5KN + K)) \).

Algorithm 2 outlines the steps to solve the max-min rate problem (36). Similar to (23) one has:

\[
\Phi(w^{(\kappa+1)}) > \Phi(w^{(\kappa)}),
\]

and like Algorithm 1, it can be shown that Algorithm 2 at least converges to a locally optimal solution of (36).

Like the problem (24) for OMA, the problem of NOMA sum throughput maximization subject to QoS constraints is formulated as

\[
\max_w \left\{ \sum_{(k,n) \in \mathcal{M}} \tilde{\rho}_{k,n}(w) \right\} \text{s.t. } (12b),
\]

\[
\tilde{\rho}_{k,n}(w) \geq \gamma_{k,n}, (k,n) \in \mathcal{M}, (47)
\]

\[\text{Algorithm 2} \text{ NOMA-IGS Max-Min Rate Optimization Algorithm}
\]

\[\text{Initialization: Set } \kappa := 0 \text{ and a feasible point } w^{(0)} \text{ satisfying the power constraint (12b)}.
\]

1: repeat

2: Solve the convex optimization problem (46) to obtain the optimal solution \( w^{(\kappa+1)} \).

3: Set \( \kappa := \kappa + 1 \).

4: until Convergence for the objective in (36).

where \( \gamma_{k,n} \) is the user \((k,n)\)'s throughput threshold. By using the expression (28) for the throughput function \( \dot{\rho}_{k,p,n}(w) \) of user \((k,p(n)) \in \mathcal{M}_c \), we can rewrite (47) by

\[
\max_w \sum_{(k,n) \in \mathcal{M}_c} \left[ \tilde{\rho}_{k,n}(w) + \min \{ \rho_{k,n}(w), \dot{\rho}_{k,p,n}(w) \} \right] \text{ s.t. } (12b), (48a)
\]

\[
\tilde{\rho}_{k,n}(w) \geq \gamma_{k,n}, (k,n) \in \mathcal{M}_c, (48b)
\]

\[
\min \{ \rho_{k,n}(w), \dot{\rho}_{k,p,n}(w) \} \geq \gamma_{k,n}(p), (48c)
\]

which can be computed by generating the next iterative feasible point \( w^{(\kappa+1)} \) as the optimal solution of the convex optimization problem

\[
\sum_{(k,n) \in \mathcal{M}_c} \left[ \tilde{\rho}_{k,n}(w) + \min \{ \rho_{k,n}(w), \dot{\rho}_{k,p,n}(w) \} \right] \text{ s.t. } (12b), (49a)
\]

\[
\tilde{\rho}_{k,n}(w) \geq \gamma_{k,n}, (k,n) \in \mathcal{M}_c, (49b)
\]

\[
\min \{ \rho_{k,n}(w), \dot{\rho}_{k,p,n}(w) \} \geq \gamma_{k,n}(p), (49c)
\]

\[\text{IV. Simulation Results}
\]

In all simulations, the channel \( h_{k', k,n} \) from BS \( k' \in \mathcal{K} \) to UE \((k,n) \) at a distance of \( d \) meters is generated as

\[ h_{k', k,n} = \sqrt{10^{-\sigma P_t / 10}} \cdot \bar{h}_{k', k,n} \]

In the above, \( \bar{h}_{k', k,n} \) is a normalized Rayleigh fading channel gain, if \( k' = k \) and \( n \in \mathcal{N}_c \) (channels between the BS and its own cell-edge users), or if \( k' \neq k \) (channels between the BS and users in neighboring cells). On the other hand, \( \bar{h}_{k', k,n} \) is a normalized Rician fading channel with a Rician factor of 0 dB if \( k' = k \) and \( n \in \mathcal{N}_c \) (channels between the BS and its own cell-centered users). The path loss (in dB) is specified as

\[ \sigma^2 P_L = 38.46 + 10\beta \log_{10}(d) \]

where the loss factor 38.46 is the free space path loss at a reference distance of 1 meter at carrier frequency of 2 GHz [42], and \( \beta \) is the path-loss exponent. For the Rician
fading channels between the BS and its own cell-centered UEs (\(k'=k \) and \(n \in \mathcal{N}_c\)), \(\beta\) is set to be 2, while for the Rayleigh fading channels, \(\beta\) is set to 3.1 [42].

For simplicity, the same power budget is set for each cell, i.e., \(P_k^\text{max} = P_\text{max}, \forall k \in K\). Unless stated otherwise, \(P_\text{max} = 26 \) dBm, and the noise power spectral density \(\sigma^2\) is \(-174\) dBm/Hz with bandwidth \(B = 20\) MHz.

To analyze the performance of the proposed algorithms, we present simulation results separately for both single-cell \((K = 1)\) and multi-cell \((K > 1)\) setups. We follow [32, Algorithm 3] for evaluating the performance of the corresponding OMA-PGS and NOMA-PGS.

### A. Results for a Single-Cell Network \((K = 1)\)

We setup a single-cell network as shown in Fig. 1, which simulates an urban micro-cellular environment with a cell radius of 300 meters, where the cell-centered UEs are placed around the distance of 110 meters from the BS while the cell-edge users are placed at a distance of about 265 meters from the BS [42]. In this subsection, unless stated otherwise, we consider \(N = 8\) UEs with four cell-centered and four cell-edge UEs and \(N_t = 6\) transmit antennas at each BS.

Fig. 2 shows the convergence of the proposed algorithms (Algorithms 1 and 2) under \(N_t = 6\) BS antennas, \(K = 1\) cell, \(N = 8\) UEs, and \(P_\text{max} = 26\) dBm. Fig. 2 shows that both Algorithm 2 (NOMA-IGS) and Algorithm 1 (OMA-IGS) converge after approximately within 40 iterations. The computational complexities of Algorithms 1 and 2 are given in Table I, which shows the rounded average number of iterations over different channel realizations, number of decision variables, and number of quadratic/LMI constraints.

Fig. 3 plots the optimized worst user rate versus varying number of BS antennas \(N_t\), for fixed \(K = 1\) cells, \(N = 8\) UEs, and \(P_\text{max} = 26\) dBm. As expected, the throughput increases with the increase in the number of antennas, thanks to the larger degree of freedom. It can be seen that an approximately two-fold gain in the throughput is obtained by employing IGS instead of PGS under both NOMA and OMA systems. However, the performance gain decreases with the increase in the number of BS antennas. One important observation from Fig. 3 is that Algorithm 2 (NOMA-IGS) and Algorithm 1 (OMA-IGS) have a similar performance when the number of BS antennas \(N_t\) is the same as the number of UEs \(N\). Fig. 4 illustrates how the optimized worst user rate decreases as the noise power spectral density \(\sigma^2\) increases for fixed \(N_t = 6\) BS antennas, \(K = 1\) cell, \(N = 8\) UEs, and \(P_\text{max} = 26\) dBm. Fig. 4 once again shows that there is a substantial gain, approximately two-fold gain, in the throughput by employing IGS instead of PGS under both NOMA and OMA systems. This performance gain is comes from the additional degree of freedom as captured via the non-zero pseudo-covariance matrix in IGS. Both Figs. 3 and 4 clearly show that NOMA-IGS (Algorithm 2) offers the best throughput compared to all other signaling/multiple access strategies under consideration.

Fig. 5 illustrates how the optimized worst user rate increases when increasing the BS transmit power budget \(P_\text{max}\), for fixed \(N_t = 6\) BS antennas, \(K = 1\) cell, and \(N = 8\) UEs per cell. Observe that the performance gap in the throughput between IGS and PGS increases with the increase in the power budget. Fig. 6 plots optimized worst user rate versus varying number of UEs \(N\), under fixed \(N_t = 6\) BS antennas, \(K = 1\) cell, and \(P_\text{max} = 26\) dBm. As expected, the throughput decreases with the increase in the number of UEs per cell due to the increase in interference. Again, both Figs. 3 and 6 show that NOMA-IGS (Algorithm 2) offers the best throughput.

### B. Results for a Multi-Cell Network \((K = 3)\)

A three-cell network is depicted in Fig. 7. The radius of each cell is 300 meters, where the cell-centered UEs in each cell are placed around the distance of 110 meters from the serving BS, while the cell-edge users are placed at about 265 meters from the serving BS. In this subsection, unless stated otherwise, we consider \(N = 4\) UEs with two cell-centered and two cell-edge UEs and \(N_t = 3\) transmit antennas at each BS.

Fig. 8 illustrates the convergence of the proposed Algorithms 1 and 2, under \(N_t = 3\) BS antennas, \(K = 3\) cells, \(N = 4\) UEs, and \(P_\text{max} = 26\) dBm. Fig. 8 shows that both Algorithm 2 (NOMA-IGS) and Algorithm 1 (OMA-IGS) converge within 25 iterations approximately. In Table II, the computational complexities of the two proposed algorithms are provided for \(N_t = 3\) BS antennas, \(K = 3\) cells, \(N = 4\) UEs, and \(P_\text{max} = 26\) dBm.

<table>
<thead>
<tr>
<th>Alg.</th>
<th># iterations</th>
<th># variables</th>
<th># constraints</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alg. 1</td>
<td>24</td>
<td>72</td>
<td>15</td>
</tr>
<tr>
<td>Alg. 2</td>
<td>26</td>
<td>72</td>
<td>21</td>
</tr>
</tbody>
</table>

Fig. 9 plots the optimized worst user rate versus varying number of BS antennas \(N_t\), for fixed \(K = 3\) cells, \(N = 4\) UEs, and \(P_\text{max} = 26\) dBm. As in the case of single-cell setup, it can be seen that: (i) the throughput increases as the number of antennas increases, and (ii) an approximately two-fold gain in the throughput is obtained by employing
IGS instead of PGS under both NOMA and OMA systems. Again, this performance gain is due to the additional degree of freedom captured via the non-zero pseudo-covariance matrix in IGS. Fig. 10 plots the optimized worst user rate versus varying number of cells $K$ under fixed $N_t = 3$ BS antennas, $N = 4$ UEs, and $P_{\text{max}} = 26$ dBm. As can be seen, the throughput decreases with the increase in the number of cells, which is expected since the inter-cell interference increases. We can observe from Figs. 9 and 10 that, also in a multi-cell network, NOMA-IGS offers the best throughput compared to all other alternative signaling/multiple access strategies under consideration.

V. CONCLUSIONS

This paper has considered the design problems of transmit beamforming to maximize the users’ max-min throughput subject to power constraints when improper Gaussian signaling (IGS) is used in multiuser multi-cell broadcast interference networks with either orthogonal multiple access (OMA) or non-orthogonal multiple access (NOMA). The computational solution for such non-convex problems is non-trivial as the throughput functions depend on a particular structure of widely linear precoding matrices. We have developed $2 \times 2$ LMI optimization based algorithms to solve these design problems efficiently. Numerical results showed that there is almost a two-fold gain in the throughput by employing IGS instead of the conventional proper Gaussian signaling (PGS), under both OMA and NOMA. When compared with other signaling/multiple access strategies, including OMA-IGS, PGS-OMA and PGS-NOMA, it offers the best throughput.
APPENDIX: THE PROOF OF LEmMA 1

Since the function \( \varphi(\mathbf{X}) \triangleq \ln |\mathbf{X}| \) is concave on the domain \( \mathbf{X} > 0 \), it is true that [39, Prop. 2.21, p. 62]

\[
\ln |\mathbf{X}| = \varphi(\mathbf{X}) \\
\leq \varphi(\bar{\mathbf{X}}) + \langle \nabla \varphi(\bar{\mathbf{X}}), \mathbf{X} - \bar{\mathbf{X}} \rangle \\
= \ln |\bar{\mathbf{X}}| - 2 + \langle \bar{\mathbf{X}}^{-1}, \mathbf{X} \rangle
\]

\begin{equation}
\tag{50}
\end{equation}

for all positive definite matrices \( \mathbf{X} \) and \( \bar{\mathbf{X}} \) of size \( 2 \times 2 \). This also means that

\[
\ln |\mathbf{X}^{-1}| = -\varphi(\mathbf{X}) \\
\geq \ln |\bar{\mathbf{X}}^{-1}| + 2 - \langle \bar{\mathbf{X}}^{-1}, \mathbf{X} \rangle.
\]

\begin{equation}
\tag{51}
\end{equation}

Making use of the fact that a matrix is positive definite if and only if its inverse is positive definite, we replace \( \mathbf{X}^{-1} \rightarrow \mathbf{X} \) and \( \bar{\mathbf{X}}^{-1} \rightarrow \bar{\mathbf{X}} \) in (51) to obtain

\[
\ln |\mathbf{X}| \geq \ln |\bar{\mathbf{X}}| + 2 - \langle \bar{\mathbf{X}}, \mathbf{X} \rangle, \quad \forall \mathbf{X} > 0, \bar{\mathbf{X}} > 0.
\]

\begin{equation}
\tag{52}
\end{equation}

Now, representing the function \( f \) defined in (14) by

\[
\ln |(\mathbf{X}_1)^2 + (\mathbf{X}_2)^2 + \sigma^2 \mathbf{I}_2| + \ln |(\mathbf{X}_2^2 + \sigma^2 \mathbf{I}_2)^{-1}|
\]
and applying inequality (52) to the first term and inequality (51) to the second term, one obtains

\[
f(X_1, X_2) \geq \ln |I_2 + [\bar{X}_1]^2 (|\bar{X}_2|^2 + \sigma^2 I_2)^{-1}| + 4 \\
- \sigma^2 ((|\bar{X}_2|^2 + \sigma^2 I_2)^{-1}) \\
- \left( \sum_{i=1}^{2} |X_i|^2 + \sigma^2 I_2, \left( \sum_{i=1}^{2} |X_i|^2 + \sigma^2 I_2 \right)^{-1} \right) \\
- ((|\bar{X}_2|^2 + \sigma^2 I_2)^{-1}, |\bar{X}_2|^2 + \sigma^2 I_2). \tag{53}
\]

Further, applying the inequality

\[
|X_i|^2 \succeq X_i X_i^T + \bar{X}_i \bar{X}_i^T - |\bar{X}_i|^2, \tag{55}
\]

which is an equivalent expression of the obvious inequality $|X_i - \bar{X}_i|^2 \succeq 0$, to the term (53) yields

\[
\begin{align*}
&\left( \sum_{i=1}^{2} |X_i|^2 + \sigma^2 I_2, \left( \sum_{i=1}^{2} |X_i|^2 + \sigma^2 I_2 \right)^{-1} \right) \\
&\leq \left( \sum_{i=1}^{2} |X_i|^2 + \sigma^2 I_2, \left( \sum_{i=1}^{2} X_i X_i^T + \bar{X}_i \bar{X}_i^T \right)^{-1} \\
&\quad - |\bar{X}_i|^2 \right) + \sigma^2 I_2^{-1}. \tag{56}
\end{align*}
\]

over the trust region (27)\(^4\), for which we have also used the inequalities $(B, X) \succeq (\bar{B}, \bar{X})$ for $B \succeq 0$ and $X \succeq \bar{X} \succeq 0$, and $0 \prec X^{-1} \prec \bar{X}^{-1}$ for $X \succeq \bar{X} \succeq 0$. Now, the RHS of (26) is obtained from the RHS of (54) upon replacing the term (53) by the RHS of (56).

\[^4\text{Since the left hand side of (55) is positive definite, it is meaningful only under the trust region (27), which constrains the RHS of (55) positive semi-definite.}\]

His research interests fall into broad areas of Communication Theory, Wireless Communications, and Statistical Signal Processing. Dr. Nguyen was an Associate Editor for the IEEE Transactions on Wireless Communications and IEEE Wireless Communications Letters during 2007-2011 and 2011-2016, respectively. He currently serves as an Associate Editor for the IEEE Transactions on Vehicular Technology, IEEE Vehicular Technology Conferences (Fall 2010, Ottawa, ON, Canada and Fall 2012, Quebec, QC, Canada), Lead Co-chair for the Wireless Access Track, IEEE Vehicular Technology Conferences (Fall 2014, Vancouver, BC, Canada), Lead Co-chair and Co-chair for the Multiple Antenna Systems and Cooperative Communications Track, IEEE Vehicular Technology Conference (Fall 2016, Montreal, QC, Canada and Spring 2018, Porto, Portugal), and Technical Program Co-chair for Canadian Workshop on Information Theory (2015, St. John’s, NL, Canada). He is a coauthor, with Ed Shwedyk, of the textbook “A First Course in Digital Communications” (published by Cambridge University Press). Dr. Nguyen is a Fellow of the Association of Professional Engineers and Geoscientists of Saskatchewan (APEGS).

Trung Q. Duong (S’05, M’12, SM’13) received his Ph.D. degree in Telecommunications Systems from Blekinge Institute of Technology (BTH), Sweden in 2012. Currently, he is with Queen’s University Belfast (UK), where he was a Lecturer (Assistant Professor) from 2013 to 2017 and a Reader (Associate Professor) from 2018. His current research interests include Internet of Things (IoT), wireless communications, molecular communications, and signal processing. He is the author or co-author of 300+ technical papers published in scientific journals (190 articles) and presented at international conferences (132 papers). Dr. Duong currently serves as an Editor for the IEEE TRANSACTIONS ON WIRELESS COMMUNICATIONS, IEEE TRANSACTIONS ON COMMUNICATIONS, IET COMMUNICATIONS, and a Lead Senior Editor for IEEE COMMUNICATIONS LETTERS. He was awarded the Best Paper Award at the IEEE Vehicular Technology Conference (VTC-Spring) in 2013, IEEE International Conference on Communications (ICC) 2014, IEEE Global Communications Conference (GLOBECOM) 2016, and IEEE Digital Signal Processing Conference (DSP) 2017. He is the recipient of prestigious Royal Academy of Engineering Research Fellowship (2016-2021) and has won a prestigious Newton Prize 2017.

H. Vincent Poor (S’72, M’77, SM’82, F’87) received the Ph.D. degree in EECS from Princeton University in 1977. From 1977 until 1990, he was on the faculty of the University of Illinois at Urbana-Champaign. Since 1990 he has been on the faculty at Princeton, where he is currently the Michael Henry Strater University Professor of Electrical Engineering. During 2006 to 2016, he served as Dean of Princeton’s School of Engineering and Applied Science. He has also held visiting appointments at several other universities, including most recently at Berkeley and Cambridge. His research interests are in the areas of information theory and signal processing, and their applications in wireless networks, energy systems and related fields. Among his publications in these areas is the recent book Information Theoretic Security and Privacy of Information Systems (Cambridge University Press, 2017).

Dr. Poor is a member of the National Academy of Engineering and the National Academy of Sciences, and is a foreign member of the Chinese Academy of Sciences, the Royal Society, and other national and international academies. He received the Marconi and Armstrong Awards of the IEEE Communications Society in 2007 and 2009, respectively. Recent recognition of his work includes the 2017 IEEE Alexander Graham Bell Medal, Honorary Professorships at Peking University and Tsinghua University, both conferred in 2017, and a D.Sc. honoris causa from Syracuse University also awarded in 2017.
