Abstract

We conducted a large international nested case-control study including 1,881 patients with Philadelphia-negative myeloproliferative neoplasms (MPN). Cases (n=647) were patients with second cancer (SC: carcinoma, non-melanoma skin cancer, hematological second cancer and melanoma) and controls (n=1,234) were patients without SC, matched with cases for sex, age at MPN diagnosis, date of MPN diagnosis and MPN disease duration.

The aim was to evaluate the risk of SC after exposure to cytoreductive drugs.

Patients exposed to hydroxyurea (HU) (median: 3 years) had a risk of SC similar to unexposed patients (OR=1.06, 95% CI 0.82-1.38). In contrast, in cancer-specific stratified multivariable analysis, HU had two-fold higher risk of non-melanoma (NM) skin cancer (OR=2.28, 95% CI 1.15-4.51). A significantly higher risk of NM-skin cancer was also documented for pipobroman (OR=3.74, 95% CI 1.00 - 14.01), ruxolitinib (OR=3.87, 95% CI 1.18-12.75) and for drug combination (OR=3.47, 95% CI 1.55-7.75). These three drugs did not show excess risk of carcinoma and hematological second cancer compared with unexposed patients. Exposure to interferon, busulfan and anagrelide did not increase the risk.

In summary, while it is reassuring that no excess of carcinoma was documented, a careful dermatologic active surveillance before and during the course of treatments is recommended.

Introduction

Polycythemia vera (PV), essential thrombocythemia (ET) and myelofibrosis (MF) are myeloproliferative neoplasms (MPN) characterized by stem cell-derived clonal myeloproliferation with mutually exclusive driver *JAK2*, *CALR*, and *MPL* mutations and other sub-clonal somatic mutations.

Current management recommendations have brought benefits in decreasing the major complications of MPN diseases and have improved overall survival and quality of life [1]. However, the proportion of MPN patients with cardiovascular events, evolution to overt myelofibrosis and acute leukemia is still elevated and the mortality rate due to these causes is higher than in normal population [2,3]. While the risk of transforming to acute leukemia has been the subject of several studies [2] less is known about the risk of developing other malignancies such as solid tumors. In this regard, the available information derives from retrospective cohort analysis [4-10] and registry-based population studies [11,12]. These latter may have limitations as they do not have access to information on individual treatment, mutational status, and other important clinical features. The relationship between cytoreductive drugs and the development of these second malignancies has been poorly explored [13,14]. The only convincing demonstration of a carcinogenic potential of cytoreductive drugs has been provided for chlorambucil and radiophosphorus in a randomized clinical trial carried out in PV by the Polycythemia Vera Study Group (PVSG) [15], whereas the evidence that other cytoreductive agents including Hydroxyurea (HU), pipobroman, busulfan and JAK2 inhibitors, may affect the risk of second cancer (SC) in MPN remains uncertain.

This topic is complex also because MPNs themselves may have an intrinsic propensity to develop cancer [12,16-18] making it difficult to distinguish the pathogenetic role of drug intervention from that of the MPN disease itself.

To tackle these relevant clinical questions, we designed a nested case-control study in the frame of European Leukemia Net (ELN). Cases were PV, ET and MF patients with SC, and controls were MPN patients who did not present or develop second malignancies during a comparable observation period.

Our aim was twofold: (i) to describe the types and frequency of SC, including hematological second cancer (HSC) and (ii) to identify the risk-factors for SC, focusing on the role of cytoreductive agents.

Patients and Methods

This multicenter international nested case-control study involved 30 international centers (18 from Italy, 11 from European centers and 1 from Israel) (*ClinicalTrials.gov: NCT03745378*).

For each center, patients with a diagnosis of Philadelphia-negative MPN according to PVSG, 2008 and 2016 WHO criteria (PV, ET, primary and secondary MF), performed from 2000 to 2016, were eligible for the study. Patients were excluded if any diagnosis of cancer occurred before the MPN diagnosis.

Selection of cases and controls

Cases were patients with SC diagnosed concurrently or subsequent to the diagnosis of MPN. Date of SC diagnosis was defined as *index date*. Controls were patients with a diagnosis of MPN without SC.

For each case with SC, up to 3 controls SC-free at the index date were matched by each center for sex, age at MPN diagnosis (± 5 years), date of MPN diagnosis (± 6 years) and MPN disease duration (± 3 years). According to the nested case-control design, each set consisting of one case and their matched-controls had a similar observational period (from MPN diagnosis until the index date) and therefore the same chance to experience the outcome.

Cases without suitable controls were excluded from this analysis.

Cytoreductive drugs exposure

For each case and control, exposure to cytoreductive drugs was assessed during the whole period from MPN diagnosis and SC occurrence (for cases)/index date (for controls).

Exposure was defined as follows: (i) exposure to a single drug, irrespective of the line of treatment; (ii) exposure to a single drug in first-line monotherapy and (iii) exposure to more than one line of treatment with cytoreductive agents.

Statistical analyses

Descriptive statistics were used for summarizing the characteristics of cases and controls at MPN diagnosis and during follow-up. Categorical variables were presented as number and percentage; continuous variable as mean and standard deviation (SD) or median and interquartile range (IQR).

Kruskal-Wallis test (for continuous variables) were used to test difference between SC cases with PV, ET and MF.

Chi-square test or Fisher's Exact test when appropriated (for categorical data) and t-test or Mann-Whitney U test (for continuous variables) were used to test differences between cases and controls.

For each type of SC, cumulative incidence over time, from MPN diagnosis, was estimated by the Kaplan-Meier method and were compared in PV, ET and MF using the log-rank test.

Conditional logistic regression models were fitted to estimate the Odds Ratio (OR) of SC (overall and stratified by the type of tumor), as well as the corresponding 95% Confidence Interval (CI), associated with cytoreductive exposure according to definition (i)-(iii). Adjustments were made for the characteristics of patients at MPN diagnosis such as age, type of MPN, duration of MPN disease, genetics data, aspirin use and the occurrence of major thrombosis and monoclonal gammopathy of uncertain significance (MGUS) during follow-up.

A sensitivity analysis was performed to evaluate the robustness of our findings by excluding SC cases (and their corresponding matched controls) without follow-up, as they were diagnosed concurrently with the MPN diagnosis.

For all hypotheses tested, two-tailed p-values less than 0.05 were considered to be significant.

Analyses were performed using STATA software, release 13 (StataCorp LP, College Station TX, USA).

Results

A. Cases

Cases with SC, stratified by type of MPN, are described in **Table 1**.

Median time to SC occurrence from MPN diagnosis was 4.5 years and the most frequent category (65.8%) was represented by carcinoma, especially of the prostate, breast, colon-rectum, and lung. A trend for a higher frequency of carcinoma in patients with ET and PV than MF was observed ($p=0.079$). The percentage of cases with NM-skin cancers, HSC and melanoma did not differ in the three MPNs. We underscore that a higher proportion of patients with MF presented with

carcinoma closer to diagnosis ($p=0.062$); moreover, in 25.8% of patients, HSC were synchronous with MPN diagnosis with a prevalence of indolent non-Hodgkin lymphoma and CLL (10 out of 16 patients). On the contrary, the synchronous occurrence was seen in only 3-4% of cases with melanoma and carcinoma and in none of patients with skin cancer. Of note, the appearance of SC in MF was persistently earlier than in PV and ET as shown in **Figure 1** which illustrates the cumulative incidence over time of the single tumor category.

B. Cases and matched-controls

Cases with SC were comparable to controls for demographics, type of MPN, and exposure to potential baseline clinical and laboratory confounders such as driver and non-driver mutations, abnormal karyotype and prior cardiovascular risk factors (**Table 2**). Of note, the proportion of patients developing major arterial thrombosis and monoclonal gammopathy of uncertain significance (MGUS) was significantly more elevated in cases than in controls ($p=0.015$ and 0.005 , respectively). No significant association was found for driver and non-driver mutations and SC.

In detail, major thrombosis after MPN diagnosis and before SC occurrence was significantly more frequent in patients with carcinoma ($p=0.034$) while the occurrence of MGUS preceding cancer was higher among cases with HSC ($p=0.000$), in particular in patients with multiple myeloma (33.3%) (**Table S1**). Interestingly, while in PV there was a trend for a higher frequency of melanoma ($p=0.077$) and carcinoma ($p=0.065$), the proportion of MF was significantly higher among cases with NM-skin cancers than controls ($p=0.040$).

C. Drug exposure

About 21.3% of cases with SC and 25.3% controls remained chemotherapy-free during the follow-up period (**Table 3 and Table S2**).

Hydroxyurea The percentage of cases treated with HU during the period from diagnosis to SC occurrence, regardless of the lines of therapy, was similar to that of controls ($p=0.793$) as well as when the drug was used alone in monotherapy ($p=0.310$). These findings were confirmed in a multivariable analysis showing that patients treated with HU, regardless of the line of treatment or

in first-line monotherapy, had a similar SC risk than patients who were not treated with this drug (OR=1.06, 95% CI 0.82-1.38 and OR=1.14, 95% CI 0.84-1.54) (**Figure 2**).

However, in cancer-specific stratified multivariable analysis, HU irrespective of the line of treatment, showed a two-fold higher risk of NM-skin cancer (OR=2.28, 95% CI 1.15-4.51) (**Figure S1**).

Moreover, a statistically significant protection of HU alone in first-line monotherapy on risk of HSC was found (**Figure S1**), even though in a sensitivity analysis (see below) this finding was not confirmed.

Pipobroman The proportion of SC cases treated with pipobroman, irrespective of the line of treatment, was significantly higher than controls ($p=0.018$) while a trend was seen for the exposure in first-line monotherapy ($p=0.061$) (**Table 3**). Notably, in multivariable analysis, the overall exposure to pipobroman, was significantly associated with the risk of SC (OR=2.10, 95% CI 1.09-4.06) (**Figure 2**), especially with NM-skin cancer (OR=3.74, 95% CI 1.00 - 14.01) (**Figure S1**).

Ruxolitinib Among cases with SC, exposure to ruxolitinib, regardless of the line of therapy ($n=58$: $n=35$ MF, $n=6$ ET, $n=17$ PV) and alone in first-line monotherapy ($n=17$: $n=16$ MF and $n=1$ ET), was significantly higher than controls ($p=0.048$ and $p=0.033$, respectively). In the multivariable analysis, the association of ruxolitinib with SC was confirmed, particularly when patients were treated as first-line monotherapy for MF (OR=4.00, 95% CI 1.23-13.06) while a trend towards a higher risk of SC was observed when the exposure to this drug was considered irrespective of the line of treatment (OR=1.68, 95% CI 0.92-3.09) (**Figure 2**). Of note, the higher risk of SC in patients exposed to ruxolitinib was limited to NM-skin cancers in which the risk was almost 4-fold higher than in non-exposed (OR=3.87, 95% CI 1.18-12.75) (**Figure S1**).

Drug combination Exposure to multiple cytoreductive drugs in combination or sequentially was more frequent in cases than in controls ($p=0.038$) (**Table 3**). However, this univariate result was not confirmed in multivariable analysis (**Figure 2 and S1**) that showed that the exposure to multiple drugs did not increase the risk of overall SC but only the risk of NM-skin cancer (OR=3.47, 95% CI 1.55-7.75).

IFN, busulfan or anagrelide The proportion of patients treated with these drugs did not differ in comparison with controls (**Table 3**). No association with the risk of overall SC was observed in multivariable model (**Figure 2**). However, as reported in the recent guidelines, caution should be employed in prescribing busulfan that is indicated at low intermittent dose in elderly [1].

D. Sensitivity analysis

To evaluate the robustness of our findings we excluded from the analysis the 35 cases with SC (and their matched controls, n = 68) without follow-up as they were diagnosed concurrently with MPN diagnosis.

We confirmed that the drugs increasing the risk of SC were pipobroman (OR=2.10, 95% CI 1.09-4.06), when considered irrespective of the line of treatment, ruxolitinib (OR=5.24, 95% CI 1.47-18.71) in first-line monotherapy and the exposure to multiple cytoreductive agents in different lines of treatment (OR= 1.46, 95% CI 1.02-2.09).

In the stratified analysis according to the type of SC, the lack of association between any cytoreductive drug and carcinoma was confirmed.

In contrast, the significant protection of HU on HSC found in the primary multivariable analysis was not confirmed when the 16 cases with concurrent hematological cancer (and their 31 matched controls) were excluded.

Discussion

The first aim of this paper was to describe second cancers (SC) observed in clinical practice of contemporaneous patients with MPN. Time of SC emergence from diagnosis was shorter in MF as compared to ET and PV and this pattern was maintained during the follow-up from diagnosis to the development of SC. Of note, in a quarter of cases, diagnosis of MPN was synchronous with hematological cancer revealing an intrinsic predisposition even in untreated MPN patients [16-18]. Therefore, although the association of MPN and SC in the same patient is a relatively uncommon event, a careful surveillance of possible co-existence of hematological malignancy in MF from the beginning of diagnosis may be indicated. A number of evidences indicate that inflammation and deranged innate immunity intervene in the pathobiology of MF at the same extent as in solid cancers [18]. Although this remains entirely speculative at present time, yet several lines of evidences indicate that, among MPN, cells from MF patients are those characterized by more overtly deranged reactive oxygen species levels and abnormal DNA repair properties [18]. In addition, the germline telomerase reverse transcriptase (TERT) rs2736100_C variant found in MPN, was identified as a susceptibility factor for a variety of solid tumors [19] and recently it has been hypothesized that co-occurrence of MPN and cancer might be attributed to a synergism between cytoreductive therapy and TERT polymorphism [20].

Cases and controls were comparable for baseline clinical and laboratory characteristics. Interestingly, the proportion of patients developing major arterial thrombosis and of those presenting with MGUS during the observation from diagnosis was significantly greater in cases than controls. This latter finding is in line with recent data reporting that the presence of MGUS in PV and ET leads to poor prognosis due to second malignancy including non-hematological solid tumors [21]. Regarding the role of thrombosis, the association of cancer with venous thromboembolism is well known [22,23]. Conversely, the association between arterial thromboembolism and occult cancer is less certain. Few studies have systematically analyzed the association between cancer and preceding arterial thromboembolic events [24]. A very recent study evaluated the risk of arterial thromboembolism before cancer diagnosis in a series of 374,331 patients with age higher than 67 years. In these non MPN cases, the risk of arterial thromboembolic events was increased up to 69% in the year before cancer diagnosis [25]. A possible biological reason for the link between arterial thrombosis and SC may be related to an underlying common pathogenetic mechanism. It has been proposed that an aberrant inflammatory response consistently found in MPN may precede both thrombosis and second cancer [18].

The second aim of our study was to investigate the pathogenetic role of cytoreductive drugs used to control the chronic phase of PV, ET, and MF. The exposure was evaluated for each of the single drugs regardless of the line of treatment, in only the first line and in association with more cytoreductive drugs.

HU was the agent most frequently prescribed and the percentage of exposed cases was not different from that of controls, considering overall SC groups. However, when the model was fitted in the single SC categories, HU was significantly associated with the appearance of non-melanoma skin cancer confirming previous uncontrolled observations [26,27] and registry data [12]. It is reassuring that, our findings did not confirm a previous report [28] that HU increases the risk of more serious cancers such as carcinoma. Similar results were obtained in a propensity score analysis of a large number of PV patients enrolled in the European Collaborative Aspirin Study (ECLAP) in which HU exposure did not enhance the carcinoma risk compared with phlebotomy alone, although the median observational period was only 2.7 years [7].

As HU continues to have a prominent role in the treatment of PV, ET and MF, clinicians must be aware that the exposure to this drug in our study was limited to a median period of 3 years (range 1.2 – 6.1) and, with this exposure duration, HU did not increase the risk of melanoma, carcinoma and HSC. Moreover, we underscore that previous reports indicate that exposure to HU at any cumulative dose level did not increase the risk of AML/MDS transformation neither in a crude analysis nor after adjustments for other treatments [29]. However, before reaching a firm conclusion in this regard, a longer follow-up is warranted.

Patients treated with pipobroman developed SC in a greater percentage than controls and, in multivariable analysis, the potential of this drug to enhance the risk was statistically significant when administered irrespective of the line of treatment (OR=2.10 (95% CI 1.09-4.06)). This and other findings reporting a leukemogenic action of this drug [30] reinforce the recommendation that it should no longer be used in the treatment of MPN.

The effect of ruxolitinib on the occurrence of SC was evaluated in 58 patients, 27 cases (4.2%) and 31 controls (2.5%) ($p=0.048$), regardless of the line of treatment and in 17 patients treated with the drug alone in first-line monotherapy, 10 cases (1.5%) and 7 controls (0.6%) ($p=0.033$). Ruxolitinib exposure was higher in cases with SC than in controls and the increased risk when the drug was used in first-line monotherapy, was confirmed in multivariable analysis (OR 4.00, 95% CI 1.23-13.06) after adjustment for age, duration of the MPN disease, type of MPN, *JAK2* mutation, appearance of a thrombotic event and MGUS during follow-up. This was also shown when the multivariable analysis was performed in patients exposed to ruxolitinib independently of the line of treatment although only a trend to enhanced risk was documented (OR=1.68, 95% CI 0.92-3.09). Types of SC associated with ruxolitinib were exclusively non-melanoma skin cancer suggesting that this *JAK1/2* inhibitor may act as immunosuppressive agent. Of note, no excess of cases with HSC including aggressive NHL in comparison with controls was documented in our series. However, this latter finding in a limited number of patients, cannot refute the recently reported results of an increased risk of NHL [31].

The hypothesis that ruxolitinib exposure may be associated with increased risk of developing cancer must be taken with great caution given the limited number of patients, but represents a signal to suggest appropriate strict pharmacovigilance programs. For the time being, the awareness that these malignancies may occur in patients receiving ruxolitinib even in the absence of previous exposure to other cytoreductive drugs, should not influence the

recommendations on its use, also because these second cancers are non-aggressive and treatable. Clearly, a careful clinical and laboratory surveillance is indicated.

The limitations of our study are intrinsic to the retrospective design and to possible residual confounders, which might have influenced the occurrence of outcomes. Moreover, a bias related to the limited follow-up and, consequently, to the limited exposure time to drugs as well as a selection bias of cases and controls cannot be excluded.

However, we highlight that this nested case-control study performed in rare diseases such as MPN, represents the most efficient way, among retrospective studies, to identify the association between exposure to drugs and outcomes especially when they occur after long observation time. Moreover, another strength of this survey is the large number of patients recruited and followed-up in a qualified network of 30 European hematological centers.

In summary, we did not show evidence that HU, administered as single drug, contributes to the occurrence of melanoma, carcinoma and HSC, while we confirm that this agent, may increase the risk of non-melanoma skin cancers. Similarly, MF patients exposed to ruxolitinib alone in first-line monotherapy or in association with other cytoreductive agents may be prone to a higher probability of non-melanoma skin cancer. Accordingly, for the time being, we recommend active dermatological surveillance before and during these therapies.

These findings urgently needs to be confirmed in appropriate studies involving larger series of patients with an adequate follow-up.

FIGURE LENGENDS

Figure 1. Time to different second cancer (SC) in each MPN disease (only for case patients)

NM-skin cancer: Non-melanoma skin cancer; HSC: Hematological Second Cancer.

Figure 2. Effect of cytoreductive drugs (according to (i) exposure to a single drug, irrespective of the line of treatment, (ii) exposure to a single drug as first-line monotherapy and (iii) exposure to more than one line of treatment) on cancer risk estimated by a multivariable conditional logistic regression model adjusted for potential confounders

OR: Odds Ratio; CI: Confidence Interval

(i) Single drug exposure during follow-up (at least one administration regardless of the line of treatment): patients could be exposed to more than one cytoreductive drug during follow-up; (ii) Single drug exposure during follow-up as a first-line monotherapy and (iii) exposure to multiple treatment lines with cytoreductive drugs.

**Significant association with second cancer risk ($p < 0.05$); The model was adjusted for age at MPN diagnosis, type of MPN diagnosis (ET/PV/MF), JAK2 status, duration of MPN disease, occurrence thrombosis and MGUS during follow-up and aspirin use.*

TABLES

Table 1. Type and staging of second cancer (SC) included in the study

NM-skin cancer: Non-melanoma skin cancer; HSC: Hematological Second Cancer; IQR: Interquartile Range

**Kruskal-Wallis test for continuous variables, chi-square test or Fisher's exact test (when appropriate) for categorical data.*

Table 2. Characteristics of 647 cases of second cancer (SC) and 1,234 controls at MPN diagnosis and major events during follow-up (before SC/index date)

IQR: Interquartile Range; mv: matching variable

**T-test for continuous variables, chi-square test for categorical data; **Tested in 142 patients.*

Table 3. Treatment of patients after MPN diagnosis and before second cancer (SC)/index date

**Chi-square test or Fisher's exact test (when appropriate) for categorical data*

*** (i) Single drug exposure during follow-up (at least one administration regardless of the line of treatment): patients could be exposed to more than one cytoreductive drug during follow-up; (ii) Single drug exposure during follow-up as a first-line monotherapy and (iii) exposure to multiple treatment lines with cytoreductive drugs.*
