Conducting atomic force microscopy images of bulk semiconducting BaTiO$_3$ surfaces show clear stripe domain contrast. High local conductance correlates with strong out-of-plane polarization (mapped independently using piezoresponse force microscopy), and current-voltage characteristics are consistent with dipole-induced alternations in Schottky barriers at the metallic tip-ferroelectric interface. Indeed, analyzing current-voltage data in terms of established Schottky barrier models allows relative variations in the surface polarization, and hence the local domain structure, to be determined. Fitting also reveals the signature of surface-related depolarizing fields concentrated near domain walls. Domain information obtained from mapping local conductance appears to be more surface-sensitive than that from piezoresponse force microscopy. In the right materials systems, local current mapping could therefore represent a useful complementary technique for evaluating polarization and local electric fields with nanoscale resolution. © 2015 AIP Publishing LLC.

Since their invention, differences in the physical principles underlying image formation in Scanning Tunneling and Atomic Force Microscopies (STM and AFM) have resulted in preconceived notions about the material characteristics that each technique can probe: transport behavior and electronic structure have been the traditional preserve of STM, while AFM has been almost exclusively associated with monitoring variations in tip-sample interaction forces. Perhaps this is why the simple realization that conducting AFM (cAFM) tips could also be used to monitor spatial variations in sample conductivity has been remarkably slow to emerge. Yet, cAFM has been found to be particularly useful in certain circumstances: for example, in identifying minority conducting phases embedded in an insulating matrix as demonstrated by the recent discovery of conducting domain walls in ferroelectrics and multiferroics. Here, STM is completely unsuitable, as the vast majority of the sample is insulating.

The magnitudes of local currents measured using cAFM are affected by both the transport characteristics of the material under investigation and the nature of the tip-sample contact. Schottky barriers are often expected; indeed, current variations can sometimes have little to do with differences in inherent sample conductivity, being dominated instead by localized alterations in barrier potentials. A striking illustration is in giant tunneling electroresistance (TER), where changes in the interfacial tunneling barrier height, caused by variations in electrical polarization in different ferroelectric domains, can result in an alteration of the measured resistance of up to 75%. Non-volatile binary memory and memristors based on this remarkable effect have been suggested. While the absolute contrast, in measured currents as a function of ferroelectric polarization orientation, is maximized in ultrathin films, it is also present when performing cAFM on bulk samples and becomes obvious when the conductivity of the bulk material is sufficiently high. This has been demonstrated in HoMnO$_3$ and will be further illustrated here.

In this paper, we show that cAFM contrast on polished surfaces of bulk semiconducting BaTiO$_3$ is strongly related to the out-of-plane polarization, inferred from piezoresponse force microscopy (PFM). Local current-voltage transport characteristics are consistent with the existence of Schottky barriers and established models can be used to extract parameters proportional to the out-of-plane component of polarization in different domains. There is even evidence that the cAFM signal contains information concerning the depolarizing fields around the surface traces of domain walls. As might be expected, the polarization detected through cAFM is strongly surface sensitive (more so than PFM). This illustrates the potential for cAFM in the nanoscale mapping of polarization, as well as the resistive switching potential of ferroelectric semiconductors, even in bulk.

Throughout this study, doped barium titanate ceramic samples, used in commercial Positive Temperature Coefficient of Resistance (PTCR) devices (Amphenol YS5139 and YS6942), were examined. Quantitative energy dispersive x-ray characterization was performed and indicated the following compositions: (Ba$_{0.85}$Cu$_{0.15}$TiO$_3$)yttria (YS5139) and (Ba$_{0.68}$Pb$_{0.02}$TiO$_3$)yttria (YS6942). The ceramics were found to be chemically homogeneous, save for slight stoichiometric variations across a few unit cells adjacent to grain boundaries. The ceramics have a relatively low bulk resistivity at room temperature (typically $10^3$–$10^4$ Ω cm), but this increases dramatically, by up to 4 orders of magnitude, on heating through the ferroelectric Curie temperature (see Figure 1(a) for the bulk resistance-temperature variation in the two ceramics studied here). This phenomenon is thought to arise from the way in which polarization can locally reduce the resistivity of grain
boundaries. The samples of ceramic were cut and chemically–mechanically polished using an alkaline alumina suspension, and their local characteristics were investigated using a number of different scanning probe microscopy (SPM) techniques. All SPM was performed on a Dimension 3100 AFM at room temperature, using Pt/Ir coated silicon tips (Nanosensors). Atomic Force Microscopy (AFM) was performed in tapping mode, Piezoresponse Force Microscopy (PFM) was performed at 20 kHz in contact, and an extended TUNA module was used for cAFM using dc voltage, again in contact mode. AFM showed the resulting surfaces to be smooth (Figure 1(b)), save for slight topographic variations associated with preferential etching of different domain variants; the link between domain orientation and topography was made obvious when the vertical PFM maps (displayed as the amplitude multiplied by the cosine of the phase, $R \cos \theta$, in Figure 1(c)) and AFM images were compared. As can also be seen in Figure 1(d), cAFM often produced current contrast that reflected both the domain structure and surface topography images. This was not due to topographic cross-talk: the absolute differences in height between the adjacent domains was of the order of nanometers and, within each domain, the RMS surface roughness was usually subnanometre.

The correlation between AFM, PFM, and cAFM data has been further illustrated, in qualitative terms, in Figure 1(e). Here, the domains with slightly elevated surface topography can be seen to correlate with out-of-plane (rather than into the plane) vertical polarization components and enhanced local currents. Qualitatively, the link between polarization and current can be understood as a result of the proximity of the positive end of the electrical dipole to the tip-ferroelectric interface: it should locally lower electron energy states, decreasing the expected Schottky barrier height and increasing observed conduction. For a more robust quantitative analysis of the correlation between the polar orientation and the local current, the phase information obtained from the vertical PFM was normalized such that in-phase piezoresponse (indicating that the vertical component of polarization is out-of-the-plane) was assigned a value of 1 and out-of-phase piezoresponse (indicating that the vertical component of polarization is into-the-plane) a value of 0. At every pixel, in the images in Figures 1(c) and 1(d), the measured local current was multiplied by this normalized value of the PFM phase and the resulting positive and negative current value distributions plotted in Figure 1(f) (and fitted to Lorentzian functions). While the two distributions do have overlap, it is clear that, on the whole, the currents expected in pixels with polarization oriented out-of-the-plane are larger than those oriented into-the-plane.

To investigate further, we used the cAFM to take a series of current-voltage ($I-V$) measurements across the width of another set of two stripe domains. The resulting $I-V$ curves as a function of position are shown in Figure 2. To see the extent to which such $I-V$ behavior can provide information on the local out-of-plane polarization, we employed a Schottky barrier analysis. Quantitatively, the effects of dipole orientation on barrier height, and consequently on current densities as a function of applied voltage, have already been considered by...

\[ \left( \frac{\ln \left( \frac{J}{K} \right)}{\ln \left( \frac{J}{K} \right)} \right)^2 = \frac{\sqrt{2q^2 N_{\text{eff}}}}{kT^2 4\pi \varepsilon_0 \varepsilon_r \varepsilon_s} \left( V + V_{\text{bi}}' \right)^{3/2} + \frac{q^3}{kT^2 4\pi \varepsilon_0 \varepsilon_r \varepsilon_s \varepsilon_s} P. \]

Here, the intercept is directly indicative of the out-of-plane polarization.

To test the validity of this linear expression and how it could be used to probe local out-of-plane polarization from cAFM mapping, we applied it to I-V data from Figure 2. As a proxy for Equation (4), \((\ln I)^2\) was plotted against \(-|V|^{1/2}\). In general, this should not be a linear function, unless \(V \gg V_{\text{bi}}'\). The difficulty is that \(V_{\text{bi}}'\) is not known, and, in any case, it varies as a function of the local out-of-plane polarization. We have, therefore, taken the pragmatic approach of identifying the linear portions of the plots of \((\ln I)^2\) against \(-|V|^{1/2}\) and, by virtue of their linearity, concluded that within these specific regions the \(V \gg V_{\text{bi}}'\) condition is satisfied. Approximately linear regions in \((\ln I)^2\) against \(-|V|^{1/2}\) for each domain are plotted in Figures 3(a) and 3(b).

Across the I-V measurements taken, the gradients of these plots varied, but they did show distinctly different distributions for each domain (Figure 3(c)). Taking the mean value of the gradient for each domain as representative of those associated with the polarizations within each domain, extrapolated intercept values for \((\ln I)^2\) at \(V = 0\) were extracted for all of the I-V measurements taken. These intercept values, which should be indicative of local polarization (Equation 4), are plotted in Figure 3(d) as a function of position. Several points can be noted: first, the domain determined to have larger positive (out-of-the plane) polarization, from analysis of currents only, is also the more conducting domain, consistent with the correlations between cAFM and...
PFM data noted previously. The treatment therefore seems to have some value. Second, there is a distinct and unusual feature close to the domain wall, where the extracted polarization appears to be enhanced on one side of the wall and suppressed on the other. We do not believe that this is related to polarization variations. Rather, we suspect that it reflects local depolarizing fields, which occur at ferroelectric free surfaces adjacent to domain walls (Figure 4). These depolarizing fields are such that they act in the same sense as the applied voltage from the cAFM tip on one side of the domain wall (the side with higher out-of-plane polarization, Figure 4(b)) and in the opposite sense on the other side (Figure 4(c)). They also increase in magnitude as the domain wall is approached. It seems, therefore, that the augmentation and diminution of field from the tip is also expressed in the intercept value of the linear $(\ln I)^2 - V^{1/2}$ plots and so both polarization and local depolarizing fields might both be directly detected using cAFM. The direct measurement of local depolarizing fields is not widely described in literature, and we believe that this finding has significance.

Certainly, cAFM could be extremely useful as a complementary technique to PFM for mapping ferroelectric semiconductors. After all, cAFM information on out-of-plane polarization does not suffer the same cross-talk issues found in PFM between cantilever “flexure” (induced by in-plane polarization parallel to the cantilever axis) and genuine out-of-plane tip movement. Moreover, our mapping suggests that cAFM is more a surface sensitive probe than PFM. Field distribution under the PFM tip is assumed to decay across roughly hundreds of nm, while the tip surface contact in cAFM represents a much narrower region being probed. In Figure 5, the AFM topography illustrates the pattern of the domains at the surface, resulting from a slight preferential etching during polishing, as mentioned above. The cAFM domain maps correlate very well with the topography. However, the domain distribution that would be inferred from the PFM map of the same area is somewhat different. Presumably, the remnant of the polished grain at the sample surface is very thin and the PFM is sampling a larger signal from domain states from a different grain beneath.

In summary, by investigating polished semiconducting BaTiO$_3$ ceramics, using scanning probe microscopy, we have demonstrated that contrast in conducting AFM is sensitive to the out-of-plane component of the ferroelectric polarization. This is consistent with the effect that polarization is expected to have on the Schottky barrier at the tip-sample interface. We have analyzed current-voltage behavior at a series of points across two adjacent stripe domains and, at each point, graphically determined a parameter, which is expected to vary with the local out-of-plane polarization. Mapping this parameter as a function of position showed not only the relative change in out-of-plane polarization but also an apparent signature of the depolarizing fields close to the domain wall. The usefulness of transport measurements, using an AFM tip in contact with the surface, for inferring electrostatic information about the ferroelectric polarization and depolarizing fields has been therefore clearly demonstrated.

**FIG. 4.** Schematic illustrations of cross-sections of two domains with different out of plane polarizations (a) showing how the depolarizing field ($E_d$), which occurs around the intersection of the domain wall and the free surface of the ferroelectric (marked by a black dot), can either augment the field from the cAFM tip ($E_{tip}$) on one side of the domain wall (b) or diminish it on the other side (c); $E_{tot}$ is the total electric field at the tip-sample contact point.

**FIG. 5.** In most sets of images, topography, piezoresponse, and measured current were strongly correlated. However, in some areas, the PFM domain maps ((c), displayed as amplitude only) differed from both the topography (a) and cAFM information (b) (area inside the green dashed lines in (c)). These differences are suspected to be due to the very different sampling depths associated with PFM electrostatic fields and the Schottky barriers that dictate current in cAFM.
