ABSTRACT

We know now from radial velocity surveys and transit space missions that planets only a few times more massive than our Earth are frequent around solar-type stars. Fundamental questions about their formation history, physical properties, internal structure, and atmosphere composition are, however, still to be solved. We present here the detection of a system of four low-mass planets around the bright (V = 5.5) and close-by (6.5 pc) star HD 219134. This is the first result of the Rocky Planet Search programme with HARPS-N on the Telescopio Nazionale Galileo in La Palma. The inner planet orbits the star in 3.0935 ± 0.0003 days, on a quasi-circular orbit with a semi-major axis of 0.0382 ± 0.0003 AU. Spitzer observations allowed us to detect the transit of the planet in front of the star making HD 219134 b the nearest known transiting planet to date. From the amplitude of the radial velocity variation (2.25 ± 0.22 m/s) and observed depth of the transit (359 ± 38 ppm), the planet mass and radius are estimated to be 4.36 ± 0.44 M⊕ and 1.606 ± 0.086 R⊕, leading to a mean density of 5.76 ± 1.69 g cm−3, suggesting a rocky composition. One additional planet with minimum-mass of 2.78 ± 0.65 M⊕ moves on a close-in, quasi-circular orbit with a period of 6.767 ± 0.004 days. The third planet in the system has a period of 46.66 ± 0.08 days and a minimum-mass of 8.94 ± 1.13 M⊕, at 0.233 ± 0.002 AU from the star. Its eccentricity is 0.46 ± 0.11. The period of this planet is close to the rotational period of the star estimated from variations of activity indicators (42.3 ± 0.1 days). The planetary origin of the signal is, however, the preferred solution as no indication of variation at the corresponding frequency is observed for activity-sensitive parameters. Finally, a fourth additional longer-period planet of mass of 1.10 ± 0.34 M⊕ and 1.08 ± 0.09 R⊕, with an eccentricity of 0.30 ± 0.17, is orbiting the star in 1842 days, on an eccentric orbit (e = 0.34 ± 0.17) at a distance of 2.56 AU.

Key words. techniques: radial velocities – techniques: photometric – stars: individual: HD 219134 – binaries: eclipsing – instrumentation: spectrographs

1. Introduction

The statistical analysis and occurrence rate of the small-mass planets in the range of super-Earth to Neptune are discussed in several studies with the main motivation of better understanding the orbital and physical characteristics of this population of planets, in order to constrain their formation processes (Mordasini et al. 2012; Benz et al. 2014). The radial velocity planet search
programme with the HARPS spectrograph on the ESO 3.6-m telescope (Mayor et al. 2003, 2011), a similar survey with the Keck telescope (Howard et al. 2010), and the NASA Kepler trans-
isit space mission (Borucki et al 2011) have contributed tremen-
dously to our knowledge of the population of small-mass/size planets around solar-type stars.

The most common planets detected by the Kepler mission peak around $2 R_p$ (Howard et al. 2012; Fressin et al. 2013; Marcy et al. 2014). Even if such planets do not exist in our solar sys-
tem, they are found around more than 30% of solar-type hosts. Furthermore, many of them are found in coplanar multiple sys-
tems (Fabrycky et al. 2014; Howard et al. 2012; Figueira et al. 2012), tightly packed close to the central star, a new challenge
for planet formation models to explain (Ogihara et al. 2015).

Over the last 12 years the extra-solar planet zoo has also been
supplied with low-mass planets detected by the HARPS GTO
planet search programme and successive subsequent ESO Large
programmes. Notable examples include HD 40307 (Mayor et al.
2009), HD 10180 (Lovis et al. 2011b), HD 20794, and HD 85512
(Pepe et al. 2011), or Alpha Cen B (Dumusque et al. 2012).
Analysis of the results by Mayor et al. (2011) provided a list of
additional super-Earth and mini-Neptunes unveiled by the sur-
vey, as well as a first statistical analysis of the properties and
occurrence rates of the super-Earths and Neptune-mass planets
around solar-type stars. These preliminary findings were con-

ermed by the excellent statistics and precision of the Kepler de-
tections (Fressin et al. 2013).

After a decade focusing mainly on the detection and the de-
termination of the occurrence rate of low-mass planets, a signifi-
cant observational effort is now dedicated to planet characteriza-
tion. Transit results provide the planets radii and in combination
with radial velocities, the mean densities of the planets can be
derived. Spectral features of exoplanet atmospheres may also be
revealed by space and ground-based high-resolution transmission
spectroscopy in the visible and near-infrared. One of the main difficulties of such characterization is the availability of
bright targets favourable for follow-up observations. In particu-
lar, the determination of exquisite planetary physical parameters
will be key to lifting the intrinsic degeneracy in the deter-
mination of planet composition when several components (gas,
silicates, metals) and chemical species are mixed in the planet
interior. This was a strong driver for transit search follow-up of
super-Earths detected with radial velocities around very bright
stars from space with the MOST, Hubble, or Spitzer space tele-
scopes (Gillon et al. 2012, 2010; Demory et al. 2015a), and for
the development of a new generation of space transit missions to
be launched within the coming decade: CHEOPS/ESA (Fortier
et al. 2014), TESS/NASA (Ricker et al. 2014), and PLATO/ESA
(Rauer et al. 2014).

In order to start to fulfil the need for good estimates of planet
physical parameters and considering the successful achieve-
ments with HARPS, a similar design has been implemented for
the HARPS-N spectrograph. The instrument was built to be
an efficient exoplanet hunter in the northern hemi-
sphere, specifically aimed at the follow-up and characteriza-
tion of the brightest transit candidates from the Kepler mission.
HARPS-N is a high-precision echelle spectrograph located at
the 3.6 m Telescopio Nazionale Galileo (TNG) at the Roque de
los Muchachos Observatory on La Palma, Spain. It was built by
an international consortium of Swiss, Italian, UK, and US part-
ners, led by Geneva university. It began operations in August
2012. Eighty nights per year for five years were granted to the
consortium for a science programme including the follow-up of
Kepler candidates at high precision, and an additional survey, the
Rocky Planet Search (RPS), to search for small planets around
bright and quiet nearby stars in the northern hemisphere when the Kepler field is down.

While waiting for the new generation of ground- and space-
based transit searches targeting bright stars, planet density
estimates from the follow-up of the Kepler candidates with
HARPS-N have already been presented in several papers (Pepe
et al. 2013; Dumusque et al. 2014; Bonomo et al. 2014; Dressing
et al. 2015). They are populating the low-radius regime of the
mass-radius relation for small exoplanets with candidates for
which precise mass and radius could be determined.

In this paper we present the first results from the Rocky
Planet Search: a planetary system around HD 219134, composed of
three inner super-Earths and an outer sub-Saturn mass planet,
with the four planets spread between 0.038 and 2.4 AU from
the central star. Thanks to the high-precision photometric observa-
tions from the Spitzer space telescope, the inner planet is ob-
served to transit in front of the star. After a short presentation
of the Rocky Planet Search programme in Sect. 2, and the stellar
properties of HD 219134 in Sect. 3, the spectroscopic and photo-
metric observations of the new system are described in Sects. 4
and 5. Section 6 provides a discussion of the stability of the sys-
tem and of the composition of the inner planet. Finally, we draw
our conclusions in Sect. 7.

2. The HARPS-N Rocky Planet Search programme

The guaranteed time observation (GTO) granted to the
HARPS-N consortium is dedicated to two programmes: i) the
confirmation of the planetary nature and the characterization of
Kepler candidates and ii) a rocky planet search (RPS). The aim
of the RPS programme is to perform a systematic search for low-
mass planets around nearby quiet stars visible from the northern
hemisphere through an intensive monitoring of the radial veloc-
ity of quiet stars at very high precision. HARPS-N is stabilized
and well-controlled in pressure and temperature to minimize in-
strumental drifts, and so to secure sub-m/s radial velocities over
long periods of time. More details on the technical aspects are
presented in Cosentino et al. (2012, 2014).

The sample: the first step in establishing the RPS programme
was to select a sample of stars best suited for long-term precise
radial velocity measurements. Uncertainties in such observations
are mainly linked to noise from three different origins: photon
noise, instrumental noise, and stellar intrinsic signals. The first
important criterion for this programme was thus to concentrate
on bright stars in our closest neighbourhood. This is also in the
interest of potential follow-up studies for the characterization
of the planet properties. The sample was thus selected from the
HIPPARCOS catalogue within a distance limit set to 18 pc\(^1\). The
second step was to focus on quiet stars. Based on the CORAVEL
data and investigation in the literature, we rejected known spec-

troscopic binaries as well as stars with $V \sin i \geq 4.5$ km$^{-1}$
and stars with $\log (R'_{\text{HK}}) \geq -4.69$ from our sample. In addition,
K dwarfs are favoured in our sample over G dwarfs because of
their lower level of stellar “noise” (p-mode, granulation and ac-
tivity jitter; Dumusque et al. 2011b). Their habitable zone is
also closer in. Adding all the criteria together, we ended up with
a sample of 51 quiet stars with a range of spectral types from G8

\[ \text{to M0. They are listed in Table 1.} \]

\[ \text{1 The limit was chosen iteratively in order to have a large enough sample} \]
\[ \text{that covers a full range of right ascension, with an overdensity during winter when the Kepler field is not visible.} \]

Observational strategy: To minimize the effect of stellar noise with short typical time scales (p-modes and granulations), we applied the observational strategy implemented for the HARPS very high-precision observations (Pepe et al. 2011). With this strategy, we observe each target with a 15-min. exposure time to damp the p-modes effect and make a second (and possibly a third) measurement of the target well-spread in time during the night to damp the effect of granulation (for more details see Dumusque et al. 2011b). For bright stars, in order to avoid saturation the 15 min on target are split into subobservations. Typical average signal-to-noise ratio (S/N) of the spectra obtained are between 200 and 400, measured at λ = 550 nm.

With continuous monitoring during the past two years of operation of HARPS-N we have acquired hundreds of precise radial velocities of the stars in the RPS sample. The typical photon-noise precision per (sub)observation is about 0.3 ms\(^{-1}\). In Fig. 1, we show the radial velocity rms for all the stars in the RPS programme. This rms naturally includes photon noise, instrumental effects (telescope, spectrograph, detector), stellar intrinsic ‘noise’, and, of course, signatures of still undetected planets. With a mode around 1.48 ms\(^{-1}\), the distribution is very similar to the one obtained for the sample of solar-type stars followed at high precision with HARPS in the southern hemisphere.

We present here the first result of the HARPS-N RPS programme: the discovery of a planetary system with a transiting planet around HD 219134.

3. Stellar characteristics of HD 219134

The very bright star HD 219134 has been extensively studied in the literature. Basic photometric properties of this star were taken from the HIPPARCOS catalogue (van Leeuwen 2007). A precise estimate of the radius of the star, \( R = 0.778 \pm 0.005 R_\odot \), is available from interferometric measurements (Boyajian et al. 2012). Combined with a luminosity of 0.265 ± 0.002 \( L_\odot \), the Stefan-Boltzmann law gives \( T_{\text{eff}} = 4699 \pm 16 \) K. We adopt this value for our photometric analysis of the transiting planet in the system in Sect. 5.

Over the past few years, the star has been the object of several studies aiming at determining photospheric parameters and chemical abundance analyses (Valenti & Fischer 2005; Mishenina et al. 2008, 2012; Kovtyukh et al. 2003; Ramírez et al. 2013; Prugniel et al. 2011). Results of these studies are given in Table 2 for comparison.

We also derived the atmospheric stellar parameters directly from the HARPS-N spectra using two approaches: one based on equivalent width (EW) determination and one using the Stellar Parameter Classification tool (SPC). For the EW approach, we followed the procedure described in Sect. 3 of Dumusque et al. (2014). We used the 2014 version of the local thermodynamic equilibrium code MOOG (Sneden 1973) together with the Kurucz grid of atmosphere models (Castelli & Kurucz 2004; Kurucz 1992), while oscillator strength values in the line list from Sousa et al. (2011) were updated in accordance with the
solar iron abundance $\log \epsilon(\text{Fe I}) = 7.50$ from Asplund et al. (2009). In order to construct high-quality spectra, spectra within the same visit (subobservation) were co-added, obtaining at the time of the analysis 88 spectra with S/Ns between 400 and 700. Equivalent widths were then measured for each of them and their mean and rms were used to determine the atmospheric parameters. We only retained the lines within the range 5 mÅ < EW < 100 mÅ and with a dispersion lower than the atmospheric parameters. Despite the quality of our spectra, the preliminary analysis resulted in a poor determination of the microturbulent velocity $\xi_V$. Following the calibration from Ramírez et al. (2013) and Tsantaki et al. (2013), we decided to fix the microturbulent velocity to $\xi_V = 0.35$. The resulting atmospheric parameters are given in Table 2, with the gravity from FeII lines already included. The derived values are given in Table 2 as well.

The mass of HD 219134, $M_\star = 0.78 \pm 0.02 M_\odot$, was estimated through the Synthetic Clusters Isochrones & Stellar Tracks tool (SYCLIST)\(^2\). SYCLIST allows the user to determine stellar parameters through a Bayesian-based interpolation of the grid of Geneva stellar evolution models. For HD 219134, we used the $T_{\text{eff}}$ taken from Boyajian et al. (2012), the apparent magnitude and parallax from the HIPPARCOS catalogue (van Leeuwen 2007), and the metallicity derived from our spectral analysis as input parameters. For the last we used the average of the values obtained from the EW and SPC approaches.

The mean activity index $\log R'_{\text{HK}}$ is estimated from the HARPS-N spectra. We derive an average value of $-5.02$ with a dispersion of 0.06 dex. To estimate the rotational period of the star we used a periodogram analysis of the activity indicators, which yields a significant peak at 42.3 days (see Sect. 4.2.3).

Table 3 summarizes the stellar parameters obtained from the various catalogues and analyses mentioned above, with the final values selected for the star when several estimates are available.

### 4. Spectro-velocimetric observations

#### 4.1. The HARPS-N data

HD 219134 has been monitored by the HARPS-N spectrograph for close to three years, from BJD = 2 456 148.7 (9 August 2012) to BJD = 2 457 195.7 (22 June 2015). To mitigate the effects of stellar oscillations, the strategy was to stay on target for 10 to 15 min. Because of the brightness of the star, the observations were split into several individual subobservations to avoid saturation. We obtained a total of 481 data points spread over 99 epochs (nightly averaged values). The nightly averaged values are shown in Fig. 2. Observations were performed using the simultaneous thorium calibration technique. The mean uncertainty on the individual RVs due to photon noise and known calibration noise is 0.4 ms$^{-1}$. This corresponds to an average S/N of 268 per pixel at $\lambda = 550$ nm. The data reduction was carried out with the latest version of the HARPS-N pipeline (DRS 3.7) using the cross-correlation technique (Pepe et al. 2002; Baranne et al. 1996). In addition to precise radial velocities, the pipeline provides parameters directly estimated from the cross-correlation function (CCF) of the spectrum: CCF full width at half maximum (FWHM), CCF contrast (minimum vs. continuum), CCF bisector span inverse slope, and Ca II activity index S and $\log R'_{\text{HK}}$ (Fig. 2).

The raw rms dispersion of the radial velocities is 3.57 ms$^{-1}$. Once de-trended from an obvious drift, the observed radial velocities still show a dispersion of 2.77 ms$^{-1}$, which is significantly above the typical dispersion of such quiet stars, calling for a search for additional coherent signals in the data.

#### 4.2. Data analysis

##### 4.2.1. Data modelling

The first step of the radial velocity data analysis consists in identifying significant periodic signals in the data. This was done using the generalized Lomb-Scargle periodogram algorithm (GLS, Zechmeister & Kürster 2009) applied to the nightly averaged radial velocity measurements to which a systematic error of 1 ms$^{-1}$ was quadratically added. False alarm probabilities were estimated through a bootstrap approach by permuting the nightly averaged data. Once a significant peak was located at a given period, the corresponding Keplerian was adjusted and
removed. The process was repeated several times until no significant peak remained. For multiple Keplerians, all parameters were re-adjusted at each step of the analysis. During the analysis, we identified one radial velocity outlier (5σ at jdb = 56.829.7) and decided to remove it to allow for a robust frequency analysis.

Following this procedure, a first low-frequency oscillation with a time scale of 1842 days was identified with a semi-amplitude of 5.05 ms$^{-1}$ and a 0.8% false alarm probability (FAP). After removing the corresponding Keplerians, two highly significant peaks were seen in the periodogram, at 3.09 and 46.66 days, with semi-amplitudes of 2.25 and 2.10 ms$^{-1}$ and FAPs smaller than 0.01% and 1%, respectively (Fig. 3). One additional peak remains at 6.76 days with a significant FAP smaller than 0.01% and a semi-amplitude of 1.14 ms$^{-1}$.

To double-check the purely frequentist approach, we also removed the corresponding Keplerian, and successively the 3.09-day, the 46.66-day and finally the 6.76-day signals. Dashed lines indicate 0.1%, 1%, and 10% levels of false alarm probability.

Notes. The four-Keplerian model is preferred since it has the lowest BIC, $\chi^2$ and residual dispersion. These values are estimated based on the maximum likelihood.

ΔBIC of 20 between two models is considered strong evidence in favour of the most complex one, which leads us to adopt the four-Keplerians as our best solution.

To obtain robust confidence intervals for the Keplerian parameters as well as an estimate of the additional noise present in the data (nuisance parameter, see below), we further probe the parameter space with a Markov chain Monte Carlo algorithm (MCMC) with Metropolis-Hasting. An abundant literature discusses in great detail the implementation of MCMC posterior sampling (Andrieu & Thoms 2008 for a pure statistical approach; Gregory 2005a,b, Collier Cameron et al. 2007; and Pollacco et al. 2008 for exoplanet searches). Our MCMC probes the following set of parameters: log $p$, $\sqrt{e} \cos \omega$, $\sqrt{e} \sin \omega$.

Fig. 2. Radial velocity (top) and activity index (bottom) time series for HD 219134.

Fig. 3. Generalized Lomb-Scargle periodogram of the radial velocities of HD 219134, after removing – from top to bottom – a long-period Keplerian, and successively the 3.09-day, the 46.66-day and finally the 6.76-day signals. Dashed lines indicate 0.1%, 1%, and 10% levels of false alarm probability.
between the orbital phase and period. The possible timing are phase folded radial velocities are shown in Figs. 4 and 5.

The orbital elements corresponding to the four-Keplerian model parameters. The deviation derived from the observation errors and a nuisance parameter super-Earths, after removing the contribution of all the other planets in the system. From top to bottom, we have the 3.09-, 6.76-, and 46.66-day periods.

log \( K \), and \( \lambda_0 \) (the mean longitude at a given epoch). For partially covered orbits, one usually prefer to probe a specific timing of the radial velocity curve instead of \( \lambda_0 \) to reduce correlations between the orbital phase and period. The possible timing are \( T_{V_{\min}}, T_{V_{\max}}, \) or \( T_{\text{periastron}} \) and the choice depends on the shape of the observed radial velocity curve.

The noise model follows a simple normal law with standard deviation derived from the observation errors and a nuisance parameter \( s \) that is also probed by the MCMC. Jeffrey’s priors are used for the period, the radial velocity semi-amplitude, and the nuisance parameter while uniform priors are used for the other parameters.

4.2.2. Orbital solution

The orbital elements corresponding to the four-Keplerian model and transit timing constraints are listed in Table 5, while the phase folded radial velocities are shown in Figs. 4 and 5.

The shortest period signal, with a radial velocity semi-amplitude of 2.25 ms\(^{-1}\) at 3.09 days, is clearly identified as a super-Earth (4.32 \( M_\oplus \)) in a circular orbit. To derive the best orbital solution, we added a gaussian prior on its transit timing (see Sect. 5 and Table 5) mainly to improve its orientation.

One additional low-amplitude signal (\( K = 1.14 \) ms\(^{-1}\)) is present at 6.76 days, corresponding to a planet with minimum mass of 2.78 \( M_\oplus \). The existence of this signal is corroborated by both the FAP and the BIC estimators, but its strength might be affected by the inaccurate modelling of the long-period signal (see below).

The third signal with a period of 46.66 days and a semi-amplitude of 2.10 ms\(^{-1}\) corresponds to a super-Earth of 8.94 \( M_\oplus \). As explained below, its origin cannot be linked to any long-term stellar activity fluctuation and is undoubtedly of planetary origin. Owing to the incomplete coverage of the orbit, both the eccentricity and the period of the planet remain moderately constrained, but still lead to a good estimate of its minimum-mass, i.e. 71 \( M_\oplus \).

4.2.3. Periodic signals: planet vs. activity-related origin

Long-period magnetic cycle: the radial velocity and activity index log \( R'_{\text{HK}} \) measurements of the star HD 219134 are shown in Fig. 2. Although both exhibit long-term variations, the log \( R'_{\text{HK}} \) time series is very stable over the first 750 days of the survey and slightly increases over the last 300 days whereas the radial velocity constantly decrease over the 1050-day observation time span. No correlation is observed between RVs and log \( R'_{\text{HK}} \) as shown in Fig. 6. The long-term trend of the log \( R'_{\text{HK}} \) is most probably related to the magnetic cycle of the star (Lovis et al. 2011a; Dumusque et al. 2011a; Meunier & Lagrange 2013) while the observed 1842-day period corresponds to a long-period companion. Moreover, at the observed level of activity, we expect a low impact of stellar activity on the observed radial velocities.

Notes. The epoch is chosen as the mid-time of the observations. For the three inner planets $\lambda_0$ is chosen as fitted parameter, while the timing at velocity maximum $T_{\text{Vmax}}$ is chosen for the outer one (see Sect. 4.2.1).

Fig. 6. Star activity index as a function of the radial velocity residuals after removing the three shorter-period planet contributions for HD 219134. No clear positive correlation is observed, contrary to what is expected in the case of magnetic cycles (Lovis et al. 2011a).

Rotation period: although different, the period of the third planet (46.7 days) is not very far from the rotational period of the star estimated from coherent variations of the activity indicators. A periodic variation of around 42.3 days is indeed observed in the log $R'_{\text{HK}}$ as well as in the CCF FWHM and in the bisector span of the radial velocities, whereas no signal appears around 46.7 days, as illustrated in Fig. 7 showing the GLS periodograms of these parameters zoomed around the periods of interest. We can therefore safely consider the 42.3 days as a valid estimation of the rotational period of the star ($P_{\text{rot}}$). Conversely, no signal at 42.3 days appears in the radial velocity data, supporting the planetary solution.

In order to avoid any misinterpretation of the stellar activity as a planetary signal, we pushed our investigations a bit further.

We first examined the yearly aliases (Dawson & Fabrycky 2010) of the at 46.7- and 42.3-day signals (Fig. 7) and confirmed that one period is not an alias of the other. In a second step, we considered several subsets of the data to check the persistence of the planetary signal over time and to mitigate the possible effects of discontinuities in the data sampling. The same features are observed. This confirms that the planetary signal at 46.7 days is present in the radial velocities at any time, and that in the same data no signal appears at the estimated $P_{\text{rot}}$ (42.3 days).

A final argument in favour of the planetary interpretation of the signal at 46.7 days is provided in Fig. 8 by the absence of a
correlation between the log $R'_{HK}$ activity index and the residuals around a three-planet solution (leaving the 46.7-day period out). Such a correlation would be expected if the radial velocity variation is induced by activity-related spots or plages on the star surface.

5. Transit detection with Spitzer space telescope

5.1. Spitzer observations

Thanks to its short period of 3.09 d, HD 219134 b has an interestingly high geometric transit probability of $\sim 9\%$. In February 2015, we requested 9.5 hr of Director’s Discretionary Time (DDT) on the Spitzer Space Telescope to continuously monitor the $2\sigma$ transit window of the planet as derived from our analysis of the HARPS-N RVs. As demonstrated by the co-detection and subsequent studies of the transits and occultations of 55 Cnc e (Demory et al. 2011, 2012, 2015b; Gillon et al. 2012) and the confirmation of the transiting nature of HD 97658 b (Van Grootel et al. 2014), Spitzer is indeed a very powerful facility to search for and measure with high precision the transits of low-mass RV planets thanks to its trailing orbit that allows it to monitor the same star continuously for a complete transit window, and to its ultra-high photometric precision (a few dozens of ppm per time interval of 30 min for 55 Cnc). Our programme was approved by the Spitzer Science Center (SSC) Director under the ID 11180 (PI: M. Gillon), and the SSC managed to schedule it for 14 April 2015, a few days before the end of the current visibility window of the star.

We observed HD 219134 at 4.5 $\mu$m with the Spitzer/IRAC detector (Fazio et al. 2004) in subarray mode (32 $\times$ 32 pixels windowing of the detector), the extremely fast Fowler sampling ($\sim 0.01$ s) maximizing the duty cycle and S/N. No dithering pattern was applied to the telescope (continuous staring). Because HD 219434 is an extremely bright star for Spitzer, we used the shortest available integration time of 0.01 s, allowing the counts to remain in the linear regime of the detector. The observations were performed on 14 April 2015 from 01h58 to 11h18 UT.

We used the recently introduced PCRS peak-up mode (Grillmair et al. 2012; Ingalls et al. 2014) which was previously used by Ballard et al. (2014) to estimate the infrared transit depth of Kepler-93 b. This mode provides enhanced accuracy in the position of the target on the detector, leading to a significant decrease of the so-called pixel phase effect, which is the most important source of correlated noise in high-S/N staring mode observation with IRAC InSb arrays (e.g. Knutson et al. 2008). The run consisted of a 9 hr science astronomical observational request (AOR) preceded by a short (30 min) AOR to allow the spacecraft to stabilize.

5.2. Data reduction

After downloading to Earth and basic calibration with the Spitzer pipeline S19.1.0, the images were made available to us by SSC through the Spitzer Heritage Archive (SHA) web interface under the form of basic calibrated data (BCD). Each subarray mode BCD is composed of a cube of 64 subarray images of 32 $\times$ 32 pixels (pixel scale = 1.2 arc second). We used the following strategy to reduce these BCDs. We first converted fluxes from the Spitzer units of specific intensity (MJy/sr) to photon counts, then aperture photometry was performed on each subarray image with the IRAF/DAOPHOT$^3$ software (Stetson 1987). We tested different aperture radii, and selected 2.3 pixels as the radius minimizing at best the white and red noises in the residuals of a short data fitting analysis. The centre and width of the point spread functions (PSF) were measured by fitting a 2D Gaussian profile on each image. The $x - y$ distribution of the measurements was then looked at, and measurements having a visually discrepant position relative to the bulk of the data were then discarded. For each block of 64 subarray images, we then discarded the discrepant values for the measurements of flux, background, and $x$- and $y$-positions using a 10$\sigma$ median clipping for the four parameters; the resulting values were then averaged, the photometric errors being taken as the errors on the average flux measurements. Finally, a 50$\sigma$ slipping median clipping was used on the resulting light curves to discard outliers (e.g. due to cosmic hits).

Our resulting light curve counted 9396 measurements. It is shown in Fig. 9, with the evolution of relevant external parameters (PSF $x$- and $y$-centre and PSF width, background). Because its time sampling $\sim 3.4$ s was much shorter than the structures of the expected transit and then the typical timescale of the Spitzer systematics, we binned the light curve to time intervals of 30 s for the sake of computational speed of the data analysis. Nevertheless, we verified with a shorter version of the data analysis procedure described below that our results are insensitive to the binning of the photometry.

5.3. Data analysis

We analysed the Spitzer photometric time-series with our adaptive MCMC code (see Gillon et al. 2012 and references therein). The assumed photometric model consisted of the eclipse model of Mandel & Agol (2002) to represent the possible transit of HD 219134 b, multiplied by a baseline model aiming to represent the other astrophysical and instrumental effects at the

---

$^3$ http://sha.ipac.caltech.edu

$^4$ IRAF is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.
source of photometric variations. We assumed a quadratic limb-darkening law for the star. We based the selection of the baseline model on the minimization of the BIC (Schwarz 1978).

Following Gillon et al. (2014), the instrumental models included three types of low-order polynomials. The first had as variables the $x$- and $y$-positions of the centre of the PSF to represent the pixel phase effect of the IRAC InSb arrays (e.g. Knutson et al. 2008). The second had as variables the PSF widths in the $x$- and/or the $y$-direction, its inclusion in the baseline model strongly increasing the quality of the fit for Warm Spitzer photometry (see also Lanotte et al. 2014). The third, optional, function was a polynomial of the logarithm of time $+ \alpha$ a slope to represent a sharp decrease of the detector response at the start of the AOR (“ramp” effect, Knutson et al. 2008). To improve the quality of the modelling of the pixel phase effect, especially the fitting of its highest frequency components, we supplemented the $x$- and $y$-polynomial with the Bi-Linearly-Interpolated Sub-pixel Sensitivity (BLISS) mapping method (Stevenson et al. 2012). The sampling of the positions in space was selected so that at least five measurements fall within the same subpixel. We refer the reader to Gillon et al. (2014) for more details.

Assuming no transit of HD 219134b, the light curve corrected for the instrumental model described above shows a transit-like structure of ~300 ppm depth that lasts ~50 min (see Fig. 10); this structure remains if higher order terms are used in the polynomial functions. Our first step was to check that this transit-like structure did not correspond to any odd behaviour of the external parameters, which was not the case (Fig. 9). Before identifying the structure with the searched transit, we nevertheless performed a large set of short MCMC analyses assuming different baseline models, and assuming or not that the structure was a transit of the planet. For each baseline model, we computed the BIC difference between the best-fit models with and without transit to estimate the Bayes factor in favour of the transit hypothesis, multiplying the likelihood term $e^{-0.5\Delta BIC}$ by 9/91, the prior transit/no-transit probability ratio. In these tests, we multiplied the photometric errors by a correction factor (CF, see below) of 2.72, the highest value that we ever encountered in our past experiences of high-precision photometry with Warm Spitzer. It corresponds to an AOR targeting 55 Cnc (Demory et al., in prep.) for which the PCRS peak-up mode did not work properly. In this way we assumed that the HD 219134 light curve was strongly affected by some correlated noise poorly reproduced by our instrumental model. In the end, the lowest value that we obtained for the Bayes factor under this extreme hypothesis was ~1000 in favour of the transit hypothesis. We could thus conclude with certainty the transiting nature of the planet.

We then performed a longer MCMC analysis to probe the posterior probability distribution of the transit parameters. The orbit of HD 219134 b was assumed to be circular in this MCMC analysis. The jump parameters of the MCMC, i.e. the parameters randomly perturbed at each step of the Markov Chains, were the following:

- The stellar mass $M_\star$, radius $R_\star$, effective temperature $T_{\text{eff}}$, and metallicity [Fe/H]. For these four parameters, normal prior probability distribution functions based on the values given in Table 3 were assumed.
- The planet/star area ratio $dF = (R_p/R_\star)^2$.
- The impact parameter $b = a \cos i/R_\star$ of the planet, where $a$ is the orbital semi-major axis and $i$ is the orbital inclination. A full-transit configuration corresponds to $b < 1 - R_p/R_\star$.
- The time of inferior conjunction $T_0$ for the planet, corresponding to the mid-time of the transit.

The limb-darkening of the star was modelled by a quadratic law (Claret 2000). Values for the two quadratic limb-darkening coefficients $u_1$ and $u_2$ were drawn at all steps of the MCMC from normal distributions with expectations and standard deviations drawn from the tables of Claret & Bloemen (2011) for the Spitzer 4.5 $\mu$m bandpass and for the stellar atmospheric parameters drawn at the same step.
Fig. 11. Spitzer photometry divided by the best-fit baseline model and binned per 0.005d = 7.2 min, with the best-fit transit model overplotted in red. Below are shown the y-shifted residuals of the fit binned per 7.2 min and 30 min intervals. Their standard deviations are, respectively, 57 ppm and 25 ppm. Over the light curve is shown the prior probability distribution function derived for the transit timing of HD 219134b from our analysis of the HARPS-N RVs.

Five chains of 100 000 steps were performed for each analysis, their convergence being checked using the statistical test of Gelman & Rubin (1992). They followed a preliminary chain of 100 000 steps performed to estimate the need to rescale the photometric errors, at the end of which the standard deviation of the residuals was compared to the mean photometric errors, and the resulting ratios $\beta_\nu$ were stored. The parameter $\beta_\nu$ represents the under- or overestimation of the white noise of each measurement. The red noise present in the light curve (i.e. the inability of our model to represent perfectly the data) was taken into account as described in Gillon et al. (2010), i.e. a scaling factor $\beta_\nu$ was determined from the standard deviations of the binned and unbind residuals for different binning intervals ranging from 5 to 120 min, the largest values being kept as $\beta_\nu$. In the end, the error bars were multiplied by the correction factor $CF = \beta_\nu \times \beta_\nu$. The derived values for $\beta_i$ and $\beta_w$ were 1.30 and 1.01, resulting in $CF = 1.32$.

Table 6 presents the resulting values plus error bars for the transit and planet physical parameters, while Fig. 11 shows the light curve corrected for the systematics, the best-fit transit model, and the residuals. We obtain a planet radius of $1.606 \pm 0.086 \, R_\oplus$, and an orbital inclination of $85.058 \pm 0.080$ degrees. Combining orbital inclination with minimum mass from spectroscopy, we finally obtain a planet mass of $4.36 \pm 0.44 \, M_\oplus$.

6. Discussion

6.1. Dynamical stability

A very important and necessary a posteriori consistency check of a planetary system characterization is needed to verify that the dynamical evolution of the system is viable on the long term, assuring the persistence of the system from the end stage of its formation (when the protoplanetary disk disappears) until its observation today. Pure n-body integrations of the four-planet system, using both the GENGA Code (Grimm & Stadel 2014) launched through the DACE interface5, and a fourth-order Hermite scheme (Makino 1991), with initial conditions derived from the parameters in Table 5, and assuming coplanarity and an inclination of 5 degrees from the transit observation, shows that the system is stable for more than $10^6$ orbits of the outermost planet.

Fig. 12. Planet mass vs. distance to the host stars for planets in the close solar neighbourhood. Transiting planets are shown as ★ in this diagram. These have good mass and radius (density) determinations thanks to their proximity. The planets detected by radial velocity only are also shown using the minimum-mass as a proxy for the mass (data taken from www.exoplanets.org).

A more complete analysis, taking into account general relativity and tides as well as longer-term secular effects, is beyond the scope of this paper. As expected, a preliminary check indicates, however, that general relativity and tides will act to limit the secular growth of the eccentricities of the inner planets, favouring the long-term stability of the system.

6.2. Bulk composition of the planet HD 219134b

HD 219134b is the nearest transiting super-Earth known today. The radius and mass of the planet have been characterized to 6% and 9% accuracy, allowing us to place tight constraints on the bulk density. It thus will become one of the best targets for internal structure and atmosphere characterization with the Spitzer and HST and the upcoming space follow-up missions, e.g. TESS, JWST, CHEOPS, and PLATO. Its position in a stellar distance vs. planetary mass diagram is provided in Fig. 12.

5 DACE is a platform of the Swiss National Centre for Competence in Research “PlanetS”, which can be accessed at http://dace.unige.ch
in comparison with the other most favourable known cases for characterization within 40 pc from the Sun and up to 35 $M_\odot$: GJ 436 b (Butler et al. 2004; Gillon et al. 2007), 55 Cnc e (Gillon et al. 2012; de Mooij et al. 2014), GJ 1214 b (Charbonneau et al. 2009), HD 97658 b (Howard et al. 2011; Dragomir et al. 2013; Van Grootel et al. 2014), GJ 3470 b (Bonfils et al. 2012; Demory et al. 2013), and HAT-P-11 b (Dittmann et al. 2009).

Combining spectroscopic and space-based photometric data, we estimate a density of 5.76 ± 1.09 g cm$^{-3}$ for the planet. This density is consistent with the value of 6.90 g cm$^{-3}$ that would be predicted for a 1.606 $R_\oplus$ planet obeying the Earth-like compositional model presented in Dressing et al. (2015).

The compositional tracks employed in Dressing et al. (2015; reproduced and updated in Fig. 13) are based on interior structure models by Zeng & Sasselov (2013) that represent small planets as fully differentiated iron cores surrounded by lower density magnesium silicate mantles. These models provide a useful framework for comparing relative planet compositions, but the absolute core mass fractions are underestimated slightly because the Zeng & Sasselov (2013) models do not incorporate the presence of lighter elements in the core and do not include water in the mantle. Accordingly, the Earth-like compositional track presented in Dressing et al. (2015) corresponds to a model composition of 83% MgSiO$_3$ and 17% Fe, whereas the actual core mass fraction of the Earth is closer to 30%. Zeng et al. (2015) have recently updated their model framework to account for the presence of lighter elements in the core and the presence of water in the mantle. Employing the new models, we find that the population of highly irradiated dense planets (HD 219134b, CoRoT-7b, Kepler-10b, Kepler-36b, Kepler-78b, and Kepler-93b) are best described by a two-component iron-magnesium silicate model with a core mass fraction of approximately 22–23%.

7. Conclusion

We have presented in this paper the first result from the Rocky Planet Search (RPS) programme conducted with HARPS-N, as a planetary system of three inner super-Earths and one outer sub-Saturn planet, hosted by the bright and nearby quiet K dwarf HD 219134. The planet separations between 0.039 and 0.23 AU called for a search of potential transits of the inner planet(s) with the Spitzer space telescope. The successful detection of the transit of HD 219134 b makes the star the closest (6.5 pc) and brightest ($V = 5.5$) star known to date with a transiting planet (super-Earth). This system is thus becoming one of the most favourable ones for follow-up observations, in order to better constrain the system architecture or to characterize the physical properties of the planets. First, it provides an excellent constraining point in the mass-radius diagram (Fig. 13) for the composition of the planet, found to be of terrestrial-equivalent composition with a core mass fraction of the order of 22%. The quality of the measurements of the radius, mass, and then mean density actually foreshadows what can be expected from the future transit missions in preparation that will target bright stars (CHEOPS, TESS, PLATO). We also know from Kepler results that multi-transiting systems of small-size planets are numerous. It is now highly suitable to search for traces of transits of the other planets in the systems. Finally, even if a potential atmosphere around the planet is expected a priori to be tiny, the brightness of the system makes it worth trying to detect features of this atmosphere in the UV, visible, and near-infrared, from space and from the ground, especially in preparation for future measurements with larger facilities (JWST, TMT).
