Channel formation during the propagation of a high-energy (120 J) and long duration (30 ps) laser pulse through an underdense deuterium plasma has been spatially and temporally resolved via means of a proton imaging technique, with intrinsic resolutions of a few μm and a few ps respectively. Conclusive proof is provided that strong azimuthally symmetric magnetic fields with a strength of around 0.5 MG are created inside the channel, consistent with the generation of a collimated beam of relativistic electrons. The inferred electron beam characteristics may have implications for the cone-free fast-ignition scheme of inertial confinement fusion.
1. Introduction

The interaction of an intense laser pulse with low-density plasma is a subject of great interest, since it sits at the core of many fundamental practical applications, including electron acceleration [1][2][3][4], ion acceleration [5][6] and high energy x-ray generation [7][8]. Another application of particular interest is inertial confinement fusion (ICF) and in particular fast ignition (FI) [9][10].

A suggested method of achieving FI is to send an extended duration intense laser pulse (up to 100 ps) through the coronal plasma surrounding the pre-compressed fuel core, prior to the arrival of the ignition pulse. This channelling pulse would ‘bore’ through the underdense plasma via the ponderomotive force resulting in a voided channel extending across the mm scale corona. This has the effect of reducing the distance travelled through an attenuating medium by the ignition pulse to reach the critical surface.

The channel forms by the interaction between the charged particles within the plasma and the steep electric field gradient of the channelling pulse. Initially the electrons within the beam’s path experience a force directed radially outwards. As the electrons move outward and create a non-neutral charge distribution the ions follow, albeit slightly later, under a sustained ponderomotive drive. This results in a charge voided channel.

In the past a number of experiments have been conducted to study the formation of laser driven channels. Many of these [11][12][13][14][15] have used short pulse durations and/or short observation times (≤1 ps and ≤200 μm respectively). Diagnostically, these earlier experiments used a range of techniques including optical interferometric methods and soft X-ray radiography.

Many of these previous experiments employed relativistic intensities which can introduce several detrimental non-linear instabilities into the system including filamentation [16][17], self-phase modulation [11][18] and transverse ‘hosing’ of the laser pulse as it propagates through the plasma [19]. It has been shown [20] that increasing the laser pulse duration can contain and prevent some of these instabilities forming. More recently it has been demonstrated via 2D particle in cell simulations [21] that by sufficiently increasing the duration of the channelling pulse it is possible to create stable mm scale channels. The simulations were concerned with an electron density range from 0.1 n_c to 1.02 n_c where n_c is the critical plasma density.

The range simulated by Li et al. [21] covered only a narrow section at the upper end of the coronal density range. Sarri et al. [22] produced stable mm scale channels over the lower end of the coronal density scale (10^4 n_c < n_e < 10^3 n_c) recorded using proton radiography. This experiment also recorded the electric field generated across the channel formed by using particle tracing simulations showing that the electric profile was consistent with the channel electron density profile i.e. the electric field peaks were situated at the same positions as the channel’s walls where charge has accumulated due to ponderomotive expulsion from inside the channel. Further simulations and experiments have been conducted using similar setups considering the effects of near critical density plasmas [23] and polarisation effects [24] upon channel formation.

Along with electric fields magnetic are also generated during channelling. These fields arise mostly due to the acceleration of electrons within the channel region. A lot of work has gone into charactering magnetic fields generated in intense laser-plasma interactions using Faraday rotation, however, these use interaction pulses with duration in the tens of fs [25][26][27]. Borghesi et al. [28] have made measurements of the magnetic fields generated in similar conditions with an interaction pulse with a duration of a couple of ps. The spatial and temporal evolution of the magnetic fields generated using longer interaction pulse durations (30 ps in work) has never been documented before. Proton radiography provides an excellent
tool to perform this task with as it enables high resolution measurements to be made in both
time and space, as demonstrated for example by Sarri et al. [29].

The structure of the paper is as follows: Section II details the experimental setup while in section III the main experimental results are discussed. Section IV describes the PIC simulations used to model the interaction and section V discusses the particle tracing analysis conducted to arrive at the conclusions stated in section IV.

2. Experimental Setup

The experiment was conducted at the Rutherford Appleton Laboratory (RAL) in Oxfordshire. The VULCAN Nd-glass laser system was used providing two chirped pulse amplified (CPA) beams; one incident upon a supersonic deuterium gas jet (interaction pulse) and one incident upon a 25 μm Au foil (probe pulse). Both pulses had a wavelength of 1053 nm. The interaction pulse deposited an energy of 120 J in a pulse duration of 30 ps onto a focal spot size of ~20 μm resulting in a focused intensity of $2 \times 10^{18}$ W/cm$^2$. This pulse was preceded by a lower energy pedestal with a typical intensity contrast of $\sim 10^{-7}$. The probe pulse carried an energy of 60 J in a duration of 1 ps onto a focal spot size of ~5 μm which resulted in an on focus intensity of $2 \times 10^{19}$ W/cm$^2$. The probe pulse was focused onto a 25 μm thick Au foil. This produced a proton beam via target normal sheath acceleration (TNSA) [31]. The protons had a Maxwellian energy spectrum with a cut-off energy of ~6 MeV; this was the highest proton energy recorded.

![Figure 1: Schematic diagram of the experimental setup. CPA 1 is the probe pulse that produces the proton beam for radiography. CPA 2 is the interaction pulse that drives the ponderomotive channelling.](image)

As the protons pass through the interaction region they are subject to deflection from the electromagnetic fields present therein. After having passed through the region to be probed the protons are recorded on a stack of Radiochromic film (RCF). The extent and form of the proton density modulation (accumulation or dispersion) is used to infer the strength and form of the fields present in the plasma channel. Another benefit of this technique is that each layer of the RCF stack will stop a different spectral slice of the proton beam implying that each layer of the RCF records a different temporal window of channel evolution. This allows a picture of both the spatial and temporal evolutions of the plasma channel to be obtained [32] with spatial uncertainty of a few μm and a temporal uncertainty of 1-2 ps.

The image observed on the RCF is a magnified projection of the interaction area. The distances between the proton source and the interaction region (i.e. the distance between the Au foil and the deuterium plasma), $l$, and the distance between the interaction region and the detector (i.e. distance between the deuterium plasma and the RCF stack), $L$, lead to a magnification on the RCF layers given by the equation,

$$M \approx \frac{L + l}{l}$$

In the above experiment $L$ is ~4.5 cm and $l$ is ~0.6 cm. This gives a total magnification of around 8.5.

3. Experimental Results

Figure 2 shows several snapshots of the channel formed in the experiment. The laser pulse propagates from left to right and exits the system at around the time captured by 2(b.). Clear
contrast can be seen between the lighter regions of the voided channel and the darker regions showing boundaries. The channel has two fainter regions at around one quarter and three quarters of the height of the image. These represent the channel’s walls and are consistent with results from previous experiments of this type. In the centre, however, there is a substantially darker

Figure 2: 3 layers of RCF capturing the interaction at times of (a.) 120 ps, (b.) 70 ps and (c.) 50 ps. The axis on the right hand side displays the co-ordinate system that is used for this and all further images and descriptions.

region which represents a region of field inversion inside the channel as mentioned in Kar et al. [33]. In this case it seems to persist for longer (>120 ps compared to just tens of ps) and is observed at lower intensity (2x10^{18} Wcm^{-2} compared to 1.5x10^{19} Wcm^{-2}). This lines constitute a deflection profile which contains information concerning the fields present within the channel. This information can be extracted via the procedure discussed in section V. Comparing the channel radius to the time associated with each layer (calculated from the energy of protons that each layer captures) it is possible to build up a picture of the channel expansion velocity. In this manner the channel expansion is found to occur at a rate of 1.3x10^5 ms^{-1} (± 8.5%) (illustrated in figure 3). This is of the same order found previously in similar experiments under similar conditions [22] and seems to confirm that channel expansion is driven solely by plasma pressure.

Figure 3: Channel radius shown as a function of time.

4. Particle-In-Cell Simulations

In order to better understand the structure of the electromagnetic fields observed in experiments a series of 2D and 3D particle-in-cell (PIC) simulations have been performed. In order to better understand the structure of the electromagnetic fields observed in experiments a series of 2D and 3D particle-in-cell (PIC) simulations have been performed with OSIRIS [34]. In OSIRIS, electromagnetic fields are stored on a discretised spatial grid. They are advanced in time according to the Maxwell's equations solved at grid points. Plasma particles, however, explore the full 6D phase space. Their motion is directed by the Lorentz force, which is calculated using the electromagnetic fields interpolated from the grid points to the particle positions. After advancing all the particles, charge and current distribution from the plasma are deposited to the grid nodes and used in the Maxwell's equations to advance the electromagnetic fields in the next iteration. An initial current density is recorded on a spatial grid and then Maxwell’s equations are solved for the same grid and stored. The fields calculated act upon the charged particles and their motion is calculated based upon the interpolation of the fields to the particles’ positions. The new particle positions are then recorded and Maxwell’s equations are solved again for the new charge density distribution. This process repeats for each time step until the simulation has ran its course.

In a typical simulation, a long laser pulse is focused at the entrance of a flat-density underdense plasma slab, which later results in a channel formation. Since the interaction times are several picoseconds, the ions are expected to move, and therefore all the simulations are performed with mobile ions. Full-scale simulations for this setup, even in 2D, require the usage of high-end state-of-the-art supercomputers because the plasma slab is long (mm scale) when compared to the optical laser wavelength (μm scale) that needs to be fully resolved. Therefore, the main analysis presented here is based on PIC simulations with two spatial dimensions. However, 3D simulations of early channel formation were performed with smaller plasma lengths, and they qualitatively agree with the 2D results. Although at later times the channel expands at a slower pace in 3D, the self-consistent field structure
(which is relevant for the conclusions that follow) is similar in 2D and 3D. Here we show the results of a 2D simulation for channel formation in the interaction of an intense laser pulse \( I = 10^{18}\text{ W/cm}^2 \), with a Gaussian spatial profile, spot-size of 15 μm and 5 ps duration (FWHM in the field amplitudes), and a background deuterium plasma \( n_0 = 10^{18}\text{ cm}^{-3} \). A scaled down pulse duration of 5 ps was chosen because running the simulation for a full duration of >100 ps with a pulse duration of 30 ps was beyond the available computational capabilities. The channelling laser pulse is linearly polarised in z (out of the simulation plane) direction. The plasma slab is 1.9 mm long and 0.8 mm wide, with a flat-top density profile that has a 30 μm linear ramp in the x direction. The simulation box is 2.87 mm long and 0.8 mm wide, where in y perpendicular direction the entire simulation box is filled with plasma and uses periodic boundary conditions. The number of cells used is 54000 x 2500, the timestep 0.16 fs and each cell contains two electrons and two ions. Total simulated time was 21.2 ps. Figure 4 shows the simulated electrostatic field distribution at three separate times. The results here are averaged over the fast-oscillating component of the laser, and therefore the fields presented correspond to the slow-varying fields of the plasma. As the incoming laser propagates through the plasma it radially expels plasma electrons via the ponderomotive force. Since ions take longer than electrons to respond, radial space charge fields appear within the plasma channel. A sheath of high plasma density (2-3 times higher density than the background plasma) surrounds a partially voided channel, which is centred on the laser axis. The space-charge radial electric field within the channel is stronger in the beginning of channel formation than at later times when the ions start to be evacuated. The ponderomotive force will be maximum at the periphery of the laser intensity profile, since there lies the maximum gradient in the square of the electric field. On the other hand, it will be extremely small, if not ideally zero, along the laser propagation axis. We thus expect a region of higher plasma electron density exactly along the laser propagation axis, whose radial oscillations can be clearly seen in Figure 4 (b).

Figure 5: Magnetic field (a-b) and the electric current density (c-d). The azimuthal self-consistent magnetic field surrounds the on-axis current filament made of electrons moving in the same direction as the laser (blue). The reverse current on the channel walls (red) reinforces the strong magnetic field within the channel, while outside of the channel it reduces its amplitude close to zero.

These oscillations are mainly driven by the azimuthal magnetic field shown in Figure 5. When the forward-moving electrons (positive x direction of propagation gives negative current, blue in Figure 5 (c) and (d)) are displaced radially away from the axis, the magnetic field induces a rotation of their momentum back towards the axis. Therefore, the current filament in the centre of the channel has a stable propagation. The electrons are mainly accelerated directly by the laser field, while the self-consistent fields of the plasma act to keep them in the region of the highest laser amplitude.

The PIC simulations thus provide a clear evidence for strong magnetic fields inside the laser-driven channel. In order to ascertain whether the observed accumulation of probing protons along the main channel axis is due to such magnetic fields, particle tracing...
simulations of the propagation of the probing proton beam through the electromagnetic fields obtained from the PIC simulations. The PIC code is the subject of the next section.

5. Particle Tracing Simulations

A particle tracing code was used to simulate the trajectories of the probing protons as they passed through the interaction area falling subject to the 3D electromagnetic fields within and produce 2D proton density maps in the detector plane. Proton trajectories are calculated as they proceed from a virtual point source to a proton detector through a region occupied by electromagnetic fields. The trajectories are calculated by numerically integrating the non-relativistic equation of motion for the protons as they travel through an area under the effects of an external B field. The interaction between protons within the probe beam is neglected as is the co-moving electron cloud.

Figure 6: Flow chart detailing the process of the particle tracer.

The electric field across the channel is measured in other work [22] and shown to strongly resemble that calculated in the PIC simulations. Therefore the electric field used is given the same form as that seen in [22]. This is a radially bi-polar electric field that peaks sharply on both sides of the channel at positions that correspond to the channel walls. The magnetic field is seen from the PIC codes to be more complex. It circulates around the centre of the channel azimuthally. By invokiing cylindrical symmetry it becomes clear that in the geometry used the magnetic field observed is comprised only of the \( \phi \) component. This results in a B field defined by the expression,

\[
B_\phi = B_0 \left[ e^{\left(\frac{\rho - r_B}{r_B}\right)^2} - e^{\left(\frac{\rho + r_B}{r_B}\right)^2} \right]
\]

Figure 7: Particle tracing y-velocity maps of protons travelling through laser-driven channels for (a.) a collimated probe beam and (b.) a divergent beam.

where \( B_0 \) is the peak magnetic field, \( \rho \) is the radial coordinate of the channel, \( r_B \) is distance between the z-axis and the peak of the field and \( L_r \) is the width (FWHM) of the field. The proton beam that probes these fields is projected from a point-like source and is divergent. This divergence is the reason that the azimuthal field may be probed as a collimated beam would experience no net deflection as it passed through the channel region. As the protons pass through the channel region they would experience a force with a direction determined by the angle they form with the magnetic field. With a collimated beam this force is equal and opposite on one side of the channel as that on the other. A proton from a divergent beam, however, possesses an initial trajectory with non-zero \( \hat{y} \) and \( \hat{z} \) components. This means that the forces experienced on one side of its transit through the channel region are not undone by the experienced on the other. This results in a net proton velocity shift based on angular trajectory. Figure 7 (a.) shows the velocity shift map for collimated protons passing through the channel region. Only protons passing the boundaries of the channel are shifted. This is because they only experience the field in a single direction. This translates as a downward shift on the bottom of the channel and an upward shift on the top with protons passing through the centre experiencing no net shift. Figure 7 (b.) shows the same map but for a divergent beam. There are velocity shifting regions inside the channel this time, however, there is a reversal of shifting direction when the \( z = 0 \) point is crossed. This corresponds to
the centre of the probe beam. Protons on the right hand side of the beam are seen to be focused towards the centre of the channel while those on the left hand side are dispersed outwards towards the boundaries. The case presented in Figure 7 (b) agrees with what is expected from PIC simulations (Figure 8).

Using expressions for the electric and magnetic fields described above particle tracing simulations were ran to determine the values for the field parameters present in the data. Using the relative modulation of the proton beam as it crossed the channel, \( \delta n / n_0 \), particle tracing simulations were compared to the experimental data (Figure 9). A very good agreement was reached for the 2nd layer of the RCF (i.e. \( \sim 120 \) ps). The electric field was found to peak at \( \sim 160 \mu m \) from the centre of the channel with a magnitude of \( 2 \times 10^7 \) Vm\(^{-1}\). The magnetic field had a peak magnitude, \( B_0 \), of \( 0.40 \pm 0.05 \) MG whilst \( r_B \) and \( L_r \) had values of \( 70 \mu m \pm 12.3\% \) and \( 65 \mu m \pm 14.4\% \) respectively. By repeating this process for the other layers it is possible to build up a picture of the magnetic field’s temporal evolution.

Overlaying this with the evolution predicted by the PIC simulations reveals a high level of agreement between the two (Figure 10.). A second shot captured with an aperture removed revealed much more detail of the early period of the channel expansion (between 1-2 pulse durations). It shows remarkably similar trends to those observed in Figure 9 (Figure 11). As the PIC simulations were scaled down temporally (as mentioned above) the x-axis of Figure 10 (a.), (b.) and (c.) are relative to the relevant pulse duration (30 ps for the particle tracings and 5 ps for the PIC simulations). (a.), (b.) and (c.) are relative to the relevant pulse duration (30 ps for the particle tracings and 5 ps for the PIC simulations).

The electron density within the voided channel is \( \sim 0.01 \) that of the unmodulated plasma giving a value of order \( 10^{16} \) cm\(^{-3}\). The electron temperature is \( T_e \sim 7 \times 10^7 \) K. These values result in an electron-electron collision frequency of \( v_{ee} \sim 1.25 \times 10^6 \) Hz and an electron conductivity of \( \sigma_e \sim 5.6 \times 10^8 \) Sm\(^{-1}\). Using these values and using the radius of the channel \((\sim 100 \mu m)\) as the magnetic field scale length the diffusion time scale of the field can be estimated at \( \tau_D \sim 2 \mu s \). This indicates that the magnetic field does not fade due to diffusion over the course of the observation, however, it is seen to evolve (Figure 10). Comparing Figure 10 (a.) and (c.) shows roughly antithetical evolutions with \( B_0 \propto 1/L_r \). Given the Gaussian nature of the magnetic field and assuming that there is no significant energy loss in the system then a reasonable approximation is \( B^2 \times L_r^2 \approx \text{constant} \). This is largely seen to be the case from Figure 10 and so the major evolution of the magnetic field is driven simply by the expansion of the channel and the stretching of the magnetic field within.

The simulations indicate that the magnetic field is generated by an electron current that runs along the centre of the channel. This concurs with the beam shown along the channel axis from the particle tracings. As discussed in section 3 laser driven channels are formed by pondermotive expulsion of charge lying within the laser’s path. Many of the electrons that are
not radially expelled experience direct laser acceleration (DLA)[35] along the \( z \) direction. This is where the electrons are accelerated by the quasistatic electric and magnetic fields induced within the channel. The laser’s electric field then accelerates the electrons that are ‘wiggling’ within the channel’s fields leading to a beam of relativistic electrons. By geometric consideration eqn. 2 is the \( \theta \) component of the magnetic field in cylindrical co-ordinates (\( \rho, \phi, z \)). The curl of \( \mathbf{B} \) then reduces to,

\[
\nabla \times \mathbf{B} = \frac{1}{\rho} \left( \frac{\partial (\rho B_\phi)}{\partial \rho} \right) \hat{z}
\]

This enables the simple calculation for the current density, \( \mathbf{J} \sim 1.5 \times 10^{12} \text{ Am}^{-2} \hat{z} \) along the centre of the channel that is consistent with a collimated electron current flowing along \( z \). Assuming relativistic electrons (i.e. \( v \sim c \)) the electron density corresponding to \( \mathbf{J} \) is, \( n_e = 3 \times 10^{16} \text{ cm}^{-3} \). The current density also gives a current of \( I \sim 7.5 \text{ kA} \) using the FWHM of \( \mathbf{J} \) as the cross-section of flow.

6. Conclusion

Presented here are the first measurements of the magnetic field produced during laser driven channel formation, using a long (30 ps) pulse, with a uniform density plasma (\( n_e \sim 10^{18} \text{ cm}^{-3} \)) conducted at the VULCAN laser facility. The magnetic field is shown to arise from an electron current which is established along the centre of the channel. The magnetic field is seen to persist within the plasma for a relatively long time after the current has died. Values for magnetic field parameters were obtained by conducting particle tracing analysis matched against radiochromic films and backed up by 2D PIC simulations.

It was seen that a peak magnetic field of 0.5 MG was achieved \( \sim 70 \text{ ps} \) into the interaction. Using the trapped magnetic field it was found that a peak relativistic electron current of \( \sim 15 \text{ kA} \) with an electron density of \( \sim 10^{16} \text{ cm}^{-3} \) was produced along the centre of the channel. PIC simulations suggest that this current was produced mainly via direct laser acceleration of electrons.

This electron current may be detrimental towards the process’s use in future FI reactions. The electron current is too weak for ignition and so may instead simply heat fuel. A potential solution to this problem may lie with the polarisation of laser radiation used in channel production. Comparing available data between channels created using linearly and circularly polarised laser pulses suggests that the production of the \( z \) electrons is inhibited by the use of circular polarisation. However the nature of the channel produced by a circularly polarised pulse may not be suitable, for the purpose of ICF, when compared to the linearly polarised case [24]. This may form the basis for some future work into the hole-boring procedure.
