12 Abstract

13 This work investigates the production of activated lignin-chitosan extruded (ALiCE) pellets
14 with controlled particle size distribution (almost spherical: dp ~500–1000µm) for efficient
15 methylene blue adsorption. The novel preparation method employed in this study successfully
16 produced activated lignin-chitosan pellets. Structural and morphological characterizations were
17 performed using BET, FTIR and SEM-EDX analyses. The influence of contact time, solution
18 pH, ionic strength, initial adsorbate concentration and desorption studies was investigated. The
19 experimental data fitted well with the Langmuir isotherm ($R^2 = 0.997$), yielding a maximum
20 adsorption capacity of 36.25mg/g. The kinetic data indicated that methylene blue (MB)
21 adsorption onto ALiCE can be represented by the pseudo second-order-model with intraparticle
22 processes initially controlling the process of MB adsorption. Overall, these results indicate that
23 the novel ALiCE offers great potential for removing cationic organic pollutants from rivers and
24 streams.

1 **1. Introduction**

2 The elimination of organic dyes from rivers and streams is a key environmental challenge [1].
3 Adsorption processes offer a mechanism for the removal and recovery of metals, dyes, oils,
4 organic mixtures and pharmaceuticals from water [2, 3]. The advantages of liquid phase
5 adsorption include: low cost, simplicity of design and operation [4], absence of sludge and
6 harmful by-product formation. This has been acknowledged by the United States
7 Environmental Protection Agency (USEPA) by classifying adsorption as one of the top control
8 methods [5]. Adsorption rates and adsorption quantities are two of the most significant
9 performance indices of any adsorption system. Hence, it is essential to design and prepare
10 efficient adsorbents which are able to remove large amount of pollutants quickly using small
11 amounts of adsorbent. Various adsorbent materials have been tested for the effective removal
12 of dye such as methylene blue (MB) include spent olive stone [6] and raw dolomite [2]. Table
13 1 provides a comparison of the adsorption capacities of various adsorbents for the removal of
14 MB dye [7-11]. Methylene blue has been explored in various medical applications including
15 antimicrobial chemotherapy, biomedical dyes for cell staining, phototherapy and cancer
16 research. Compared to other toxic materials and dyes, MB is not a particularly hazardous
17 compound, though, large doses of MB (>7.0 mg/kg) can cause high blood pressure, mental
18 disorder, nausea, abdominal pain, etc. [12]. Also, MB can be freely photo-sensitized by white
19 light producing very reactive singlet species i.e. oxygen ($^1\text{O}_2$). These singlet oxygens can cause
20 destruction to the DNA structures, especially at high concentrations and, ultimately, spread to
21 the food chain. Pure lignin and chitosan have been employed individually and blended to
22 remove dyes from aqueous solutions. Chitosan is a biopolymer with many advantages: non-
23 toxicity, biocompatibility and biodegradability that can be obtained from the N-deacetylation
24 of chitin. However, chitosan is expensive, chemically unstable and can easily agglomerate .
25 Lignin is an amorphous aromatic polymer with complex structure formed by phenylpropane

1 units. Lignin is well known as a cheap waste by-product from paper and wood mills. The
2 structural units of lignin vary depending on the source of biomass from which lignin is
3 extracted. The development of bio-composites and blends containing chitosan and lignin by-
4 product as adsorption materials will decrease the total cost of the adsorbent due to decrease in
5 the usage of costly chitosan, and offer a chance for exploiting the renewable by-products
6 produced in industries. Generally, composite/blended adsorption materials are prepared by
7 using many organic solvents, acid/basic and ionic solutions.

8 This paper investigates the development of a novel adsorbent, activated lignin-chitosan
9 extruded (ALiCE) pellets, for dye adsorption. In this study, the preparation method used very
10 few solvents and was easily operated in a continuous mode (extrusion). Also, the produced
11 material had a targeted particle size, effectively attracted the methylene blue dye with high
12 adsorption capacity and exhibited superior physical and chemical stabilities. A targeted particle
13 size means that the adsorbent can be explicitly manufactured to suit specific applications of
14 water treatment; pilot plant packed columns. The lignin-chitosan materials were blended and
15 extruded with acetic acid before thermal activation under N₂ gas to enhance the mechanical and
16 physicochemical properties of the extrudates. Then, the application of the prepared activated
17 lignin-chitosan extrudates (ALiCE), as an adsorption material for methylene blue, was
18 investigated. The influence of experimental conditions such as contact time, initial pH, ionic
19 strength and dye concentration on the adsorption were elucidated and the adsorption kinetics
20 were calculated to establish the efficiency of these novel materials.

21 **2. Material and procedure**

22 Lignin (Alkali low sulfonate content), chitosan (95% deacetylated), methylene blue
23 (C₁₆H₁₈ClN₃S; MW 319.85 g/mol) and acetic acid ≥99% were obtained from Sigma–Aldrich,
24 UK. Deionized water (resistivity 18.24 Ω·cm) was used to prepare synthetic dye solutions.

2.1. Preparation of activated lignin-chitosan extrudates (ALiCE)

A Caleva mini mixer (Multi Lab: serial number 800106) with a 30cm³ stainless steel bowl, within which are two contra-rotating blades with a 0–100rpm rotational speed, was used to prepare the lignin–chitosan blends. An accurately weighed 20g of lignin and chitosan (10g of each) was mixed for 3min at 60rpm to obtain a uniform powdered mixture. Then, the mixture was further granulated with 20cm³ of aqueous acetic acid (10% v/v) solution for 10min at 60rpm, followed by extruding the wet mass at 60rpm using a Caleva single extruder (MSE: serial number 1037) fitted with a round-shaped screen (8 holes: perforation diameter: 1mm & thickness = 0.2mm). The extrudates were then spheronised for 5 mins in a Caleva spheroniser (MBS: serial number 251101) containing a friction plate with cross-hatched geometry to produce pellets with a size range of ~500–1000µm. Finally, the wet pellets were dried overnight at 80°C, followed by activation in a three zone tabular furnace (TZF 12/65/550) under nitrogen atmosphere. Activation conditions were as follows: material mass = 5g; 2 hours @ 200, 400 and 600°C (ramp rate of 20°C/min); N₂ at a flow rate of 56cm³/min. The activated lignin–chitosan extruded (ALiCE) material was finally rinsed with deionized water after which it was dried at 80°C for 12 hours before use.

2.2. Characterisation of ALiCE adsorbent

The surface area of the ALiCE was calculated from N₂ adsorption measurements completed at liquid N₂ temperature, 77 K, using the Brunauer, Emmett and Teller (BET) equation. Fourier transform infrared spectroscopy (FT-IR), energy dispersive X-ray analysis (EDX) and scanning electron microscopy (SEM) were employed to examine the surface characteristics before and after adsorption using a Perkin Elmer Spectrum 100 within the range of 400–4000 cm⁻¹ and JEOL-JSM 6400 scanning microscope, respectively. The zeta potential measurements were carried out using a Malvern zetasizer. The oxygenated acidic and basic surface groups were determined using the Boehm's titration method [13]. Single pellet diametric compression

1 measurements were performed using a TA.XT2i Texture analyser materials testing machine
2 with a PC for real time data logging and analysis.

3 **2.3. Batch studies**

4 All the experiments were performed with artificial wastewater stock solution of $1000\text{mg}/\text{dm}^3$
5 prepared by dissolving a precise amount of methylene blue in deionized water. Experiments
6 were performed by mixing 0.05g of ALiCE adsorbent with 25cm^3 of MB solutions in a 50cm^3
7 screw type glass jar at room temperature ($\sim 20^\circ\text{C}$). The pH of MB solutions is obtained using
8 a pH meter (Orion 3-Star). Good contact is made between ALiCE adsorbent and MB solutions
9 by agitating at 110rpm on a mechanical shaker (Gerhardt type LS5). The MB adsorption was
10 investigated at pH (2–9) with C_o of $43.65\text{mg}/\text{dm}^3$ and dosage $2.0\text{g}/\text{dm}^3$, initial MB
11 concentrations ($10.15\text{--}82.01\text{mg}/\text{dm}^3$). After equilibrium, the adsorbent was isolated from the
12 MB solution by centrifugation at 5000rpm for 5min . MB concentrations were obtained
13 spectrophotometrically by detecting the absorbance at $\lambda_{\text{max}} = 664\text{nm}$ using a Perkin Elmer
14 LAMBDA 25, UK. For the contact time experiments at different MB concentrations, 10.15--
15 $82.01\text{mg}/\text{dm}^3$, the same conditions were applied (optimal pH = 7 and room temperature $\sim 20^\circ\text{C}$),
16 and the solution volume used was 250cm^3 . The q_e values obtained from the contact time
17 experiment were used to construct the q_e vs C_e plots and the isotherm analysis at 20°C . In order
18 to study the effect of ionic strength: LiCl, KCl and NaCl salts were added to MB solutions at
19 pH = 7, $C_o = 43.65\text{mg}/\text{dm}^3$ and 20°C . Adsorption experiments were performed in duplicate
20 and average values were reported. The standard error was less than 5%. Desorption experiments
21 were carried out in order to investigate the regeneration of the adsorbent and evaluate the
22 mechanism involved in MB adsorption. The loaded ALiCE sample from the pH experiment
23 (pH = 7) was used for the desorption study. Loaded ALiCE was immersed in 25cm^3 of
24 desorbent solutions: 0.11M HCl, deionised water and 0.1M NaOH and the suspensions were
25 shaken for 12h . After that, the ALiCE material was separated and the amount of MB desorbed

1 was computed. Finally, it is worth mentioning that after adsorption-desorption process, the
2 adsorbent pellets remained intact.

3 2.4. Theory of adsorption, isotherms and kinetics

4 Methylene blue uptake, q (mg/g), and percentage of removal (%) were obtained according to
5 Eq. (1) and (2), respectively:

$$6 \quad q = \left[\frac{C_o - C_e}{M} \right] \times V \quad (1)$$

$$7 \quad \text{The percentage removal} = \left[1 - \frac{C_e}{C_o} \right] \times 100\% \quad (2)$$

8 where C_o is the initial and C_e is the equilibrium concentration of methylene blue (MB) in mg/
9 dm^3 , M is the amount of adsorbent in grams and V is the volume of the MB solution in dm^3 .

10 The Lagergren's pseudo-first and second-order [14, 15] and intraparticle diffusion [16] models
11 were used to describe the kinetic data tested:

$$12 \quad q_t = q_e \left(1 - e^{-k_1 t} \right) \quad (3)$$

$$13 \quad q_t = \frac{k_2 q_e^2}{(1 + k_2 q_e t)} t \quad (4)$$

$$14 \quad q_t = k_{id} \times t^{1/2} + C \quad (5)$$

15 where k_1 (1/min) and k_2 (g/mg min) are the pseudo-first-order and the pseudo-second-order rate
16 constants, respectively. k_{id} is the intraparticle diffusion rate constant (mg/(g min^{1/2})) and C the
17 intercept related to the boundary layer effect. The adsorption initial rates were calculated from
18 pseudo-first and second-order models by using the equations:

$$19 \quad h_{0,1} = k_1 \times q_e \quad (6)$$

$$20 \quad h_{0,2} = k_2 \times q_e^2 \quad (7)$$

1 The isotherm adsorption data was represented by a number of isotherm equations namely:
2 Langmuir [17], Freundlich [18], Redlich-Peterson [19] and Sips [20] adsorption isotherm
3 models:

4 Langmuir isotherm: $q_e = q_{\max} \left[\frac{bC_e}{1+bC_e} \right]$ (8)

5 Freundlich isotherm: $q_e = K_F C_e^{1/n}$ (9)

6 Redlich-Peterson isotherm: $q_e = \frac{K_R C_e}{1 + a_R C_e^\beta}$ (10)

7 Sips isotherm: $q_e = q_{\max} \left[\frac{K_s C_e^{n_s}}{1 + K_s C_e^{n_s}} \right]$ (11)

8 where q_{\max} (mg/g) and b (dm³/mg) are the Langmuir isotherm constants; K_F (mg/g (dm³/mg)^{1/n})
9 and $1/n$ are related to the adsorption capacity of the adsorbent and adsorption intensity,
10 respectively; K_R (dm³/g), a_R and β are the Redlich-Peterson isotherm constants, where: $0 \leq \beta \leq$
11 1. The Sips isotherm: K_s (dm³/mmol) is associated with the energy of adsorption and n_s indicates
12 the system heterogeneity.

13 The fundamental characteristics of Langmuir isotherm, defined by Webber and Chakkravorti
14 [21], can be expressed by a dimensionless constant called separation factor, R_L :

15 $R_L = \frac{1}{1 + bC_o}$ (12)

16 R_L indicates the shape of isotherm as follows: and $R_L = 0$ (irreversible); $R_L > 1$ (unfavourable);
17 $R_L = 1$ (linear); $0 < R_L < 1$ (favourable).

18 3. Results and discussion

19 3.1. ALiCE characteristics

20 One of the main objectives of this study is to prepare activated carbon with targeted size and
21 high mechanical strength. The final ALiCE pellets were semi spherical with diameters from

1 400–800 μ m and approx. 1mm long. The char yields after 200, 400 and 600 $^{\circ}$ C carbonization
2 were 67.7, 61.3 and 56.4 wt%, respectively. However, the prepared ALiCE adsorbent particles
3 at 600 $^{\circ}$ C are the most robust with the highest mechanical strength and lowest dust content even
4 in comparison to commercial activated carbon, AC (Filtrisorb FS-400). The calculated failure
5 loads for the ALiCE at 200, 400, 600 $^{\circ}$ C and for AC are 5.463, 7.332, 9.597 and 8.218N,
6 respectively. Based on that, the ALiCE prepared at 600 $^{\circ}$ C was used in the adsorption
7 experiments. The specific surface area of ALiCE was calculated as 80.77 m²/g, which is larger
8 than that for chemically prepared lignin-chitosan blends (2.44m²/g) [22], pZ4 activated sample
9 (25.19m²/g) and smaller than pP6 activated sample (1041.43m²/g) prepared in [23]. Adsorbent
10 surfaces could comprise chemical functional groups of acidic or basic nature. Such groups often
11 have an effect on the adsorption process of pollutants in wastewater. The acidity and basicity
12 of ALiCE surface values were calculated as: acidity = 0.279 mmol/g and basicity = 0.047
13 mmol/g. It is obvious that the acidic characteristic of ALiCE is higher than its basic
14 characteristic. It is known that, carbons with high oxygen content show acidic surface properties
15 and cation exchange behaviour.

16 **3.2. Effect of solution pH and ionic strength**

17 The adsorption removal capacity depends on the adsorbent surface properties and adsorbate
18 structure which are greatly affected by pH. The measurements of zeta potential and influence
19 of the pH solution value on adsorption of the MB was investigated and the results are illustrated
20 in Figure 1. At natural pH, the zeta potential measured for ALiCE adsorbent is approx. –20mV.
21 This value indicates that ALiCE surface is negatively charged. Starting from the ALiCE natural
22 pH, altering the pH of MB solutions indicates the difference of the zeta potential against the
23 pH of the aqueous phase in the range 2–9. The MB removal efficiency increases slightly with
24 an increase with the pH value from 2 to 4, and then the efficiency to some extent rises when
25 the pH elevated from 4 to 7. The maximum adsorption percentage removal was 87.69% at pH

1 7. Additional increase in the pH beyond 7 consequences in a small reduction in the removal
2 effectiveness. At high pH values, the presence of high concentrations of OH⁻ ions increases the
3 negative charge on the ALiCE surface by deprotonating the positively charged sites. These
4 phenomena are attributed to the value of the measured zeta potential. The negative charge value
5 was sharply enhanced when the initial solution pH was increased from 5 to 7. At pH values >
6 7, the ALiCE surface has more anionic charges, and the surface would participate in cation
7 attraction and cation exchange reactions. Thus, the barrier to dye molecules diffusion decreases
8 and results in a high adsorption capacity due to the significantly high electrostatic attraction
9 which occurs between the positive dye molecules and the negatively charged ALiCE surface.
10 Finally, at low pH, while the ALiCE less negative surface does not favour the adsorption
11 process as a result of the electrostatic repulsion, a substantial amount of dye adsorption onto
12 ALiCE still takes place at low pH values. This indicates that other mechanisms other than
13 electrostatic attraction are operative for the MB adsorption onto ALiCE. The effect of ionic
14 strength was investigated by adding LiCl, KCl and NaCl salts to the MB solutions. It was found
15 that the cations can change the surface property of ALiCE in the order K⁺ > Na⁺ > Li⁺. The
16 adsorption efficiency slightly decreased from 87.69 to 81.12, 83.42 and 84.07 due to the
17 addition of K⁺, Na⁺, Li⁺, respectively. The hydrated radius of K⁺ = 2.32 Å which is smaller than
18 Na⁺ = 2.76 Å and Li⁺ = 3.4 Å. This explains the stronger competition between MB⁺ and K⁺ and
19 as a results the more obvious influence on MB adsorption compared with the other two cations.
20 However, the small reduction in the MB adsorption efficiency indicates the selective adsorption
21 of ALiCE for MB. Similar trends have been reported for Adsorption of methylene blue onto
22 multiparous palygorskite modified by ion beam bombardment [24].

23 **3.3. Effect of contact time and initial concentration**

24 The effect of exposure time on the performance of ALiCE in adsorbing MB was investigated
25 at different concentrations, 10.15 to 82.01 mg/dm³. As shown in Figure 2, the MB adsorption

1 uptake values increased from 4.60 to 27.90mg/g, due to the increase in the driving force from
2 the concentration gradient. The adsorption process was fast in the initial phase ~150min and
3 the adsorption capacities increased quickly. Subsequently the adsorption of MB sustained at a
4 slower rate until the adsorption rate attained a constant value at its maximum level after approx.
5 40h of reaction; maximum levels were found for all concentrations as shown in Figure 2.
6 The fast initial adsorption rates are attributed to the high number of accessible free functional
7 groups e.g. -OH and -NH₂ on the surface of the ALiCE adsorbent at the start of the adsorption
8 process and less steric hindrance for the approaching dye molecules. The slow adsorption
9 process is a result of the reduction in the available adsorption positions and the build-up of MB
10 molecules on the surface of the ALiCE adsorbent; this hinders the diffusion of more MB
11 molecules into the ALiCE pores. Slow diffusion rates are related to pores which are of a similar
12 size to the diffusing molecules [25]. Furthermore, in order to demonstrate how near the
13 processes at any time are to equilibrium, the values of the fractional uptake $f(q_t/q_e)$ were plotted
14 against time t (Figure 2B). Figure 2B illustrates that the fractional uptakes f decrease and the
15 time necessary to achieve equilibrium increases with increased initial MB concentrations.

16 **3.4. Kinetic modelling**

17 The kinetic results were fit to Eqs. (3) and (4) using SigmaPlot 11.0 nonlinear regression
18 software; the fitting results and the values of the calculated constants are shown in Figure 2A
19 and Table 2, respectively.

20 It was found that k_1 and k_2 of the pseudo-first and second-order rate constants decrease with an
21 increase in the MB concentration (C_0) values. This is attributed to competition between higher
22 levels of MB molecules for the adsorbent active sites. The tendency that k_1 declines with
23 increasing C_0 suggests that it is quicker for a system with a lower C_0 to attain a definite
24 fractional uptake. This phenomenon is supported by the trends in plots in Figure 2B. From
25 Figure 2A, the first-order equation of Lagergren has described the kinetic data over the early

1 stage of the adsorption processes only, especially at high MB concentrations but not over the
2 entire contact time. Conversely, kinetics of the adsorption of MB onto ALiCE best fit the
3 pseudo-second-order model for the whole contact time range with correlation coefficient, R^2 ,
4 values close to unity and agreeing well with calculated adsorption capacities, q_e , with the
5 experimental data q_{exp} . This indicates that the adsorption mechanism depends on the adsorbent
6 and adsorbate, and the chemisorption is the rate-controlling step containing valence forces
7 through the exchange/sharing of electrons. The calculated values of $h_{0,1}$, $h_{0,2}$ as well as the rate
8 constant of external mass transfer, k_s , at the start of adsorption (determined from the plots of
9 C_t/C_0 against time at various C_0 values (plots are not shown here)) are revealed in Figure 3.

10 The overall trend observed in Figure 3 is a decline in the initial rates of adsorption with increase
11 in the initial MB concentrations. The decrease of k_s with increasing C_0 was previously reported
12 for dye adsorption and as before is attributed to the MB dye molecules competing for accessible
13 surface area. This competition appears to have more impact on the adsorption initial rates than
14 the increasing driving force caused by higher dye concentration. Also, it was observed that the
15 estimation of the adsorption initial rate by k_s is more consistent than $h_{0,1}$ and $h_{0,2}$. This is due to
16 (i) k_s is calculated without any hypothetical assumptions regarding the adsorption mechanism:
17 it is obtained directly from the temporal change of C_t/C_0 ; (ii) k_s is accurately calculated at $t =$
18 0, from fitting C_t/C_0 values for a short time at the start of adsorption, whereas $h_{0,1}$ and $h_{0,2}$ are
19 calculated from estimates of q_e and k throughout the entire adsorption period.

20 **3.5. Diffusion parameters**

21 The entire process of adsorption can be divided into four major steps: (i) dye molecules travel
22 from the bulk solution to the adsorbent surface by bulk diffusion. The transport of dye
23 molecules through the boundary occurs due to random molecular motion of individual
24 molecules [26]; (ii) film diffusion; (iii) intra-particle or pore diffusion of the dye (iv) chemical
25 reaction or complex formation [27]. The plots of the intraparticle diffusion (Eq. 5) display

1 multi-linearity, demonstrating three stages which are taking place, related to steps (ii), (iii) and
 2 (iv) (Figure 4A). Stage (i) occurs too quickly to be observed. The time needed for the second
 3 step is typically related to the changes in the system (i.e. temperature, adsorbent particle size
 4 and solute concentration, and), which make it complicated for prediction or control [28]. The
 5 calculated k_{id} values are presented in Table 3. It can be seen that the rate constants for
 6 intraparticle diffusion increased with increasing MB initial concentrations which are
 7 attributable to the greater driving force at higher C_o values. At the beginning of the diffusion
 8 process (short times), Fick's law reduces to Equation 13 [29, 30]:

$$9 \quad \frac{q_t}{q_e} = 6 \left(\frac{D_1}{\pi r^2} \right)^{0.5} t^{0.5} \quad (13)$$

10 where D_1 is the film diffusion and r is the radius of the ALiCE particle.

11 For longer times, the relationship between weight uptake and diffusion can be described by the
 12 approximated Boyd model [31]:

$$13 \quad Bt = -0.4977 - \ln(1 - F) \quad (14), \quad \text{where } F = q/q_e,$$

14 The intraparticle (pore) diffusion, D_2 (cm²/s), can be determined by plotting Bt against time;
 15 from the equation: $Slope = B = \pi^2 D_2 / r^2$ (15)

16 The rate of mass transfer is controlled by pore diffusion if the plots of Bt vs t at different MB
 17 concentrations linearly pass via the origin. If the plots are either linear or nonlinear and do not
 18 pass through the origin, the adsorption rate is ruled by chemical reaction or film diffusion [32].

19 From Figure 4B, it can be confirmed that the adsorption rate is not limited by pore diffusion
 20 during the initial period as the plots do not pass through the origin and that film diffusion or
 21 chemical reaction limits the rate of adsorption through this early stage [32]. However, for longer
 22 MB adsorption times pore diffusion is the controlling process. Results show that the film and
 23 pore diffusion decreased as the initial MB concentration increased. The decrease in D_1 and D_2
 24 with increasing MB concentration is attributed to a reduction in the number of available open

1 sites for adsorption with increasing initial concentration. The results also show that the film
2 diffusion is faster than the pore diffusion. Diffusion coefficients in the order of 10^{-6} to 10^{-8} are
3 found when the rate is governed by film diffusion whereas the diffusion coefficients are in the
4 order of 10^{-11} to 10^{-13} when the rate is controlled by pore diffusion [33]. Based on the diffusion
5 coefficients magnitudes in Table 3, both film and intraparticle (pore) processes are initially
6 involved in the MB adsorption process and that pore diffusion is the sole controlling process
7 over longer periods.

8 **3.6. Equilibrium isotherms**

9 The equilibrium data was tested by Langmuir, Freundlich, Redlich–Peterson and Sips
10 isotherms and the plots are illustrated in Figure 5A. The isotherms constants are shown in
11 Table 4. As can be observed from Figure 5A and Table 4, apart from the Freundlich isotherm
12 equilibrium, the equilibrium data fitted well to all isotherm models with a correlating constant
13 (R^2) higher than 0.99. The good fit of experimental equilibrium data of the adsorption of MB
14 onto ALiCE to the Langmuir isotherm indicates the chemisorption and monolayer adsorption
15 onto the ALiCE surface where adsorption sites are identical with similar affinities. The
16 maximum adsorption capacities calculated by Langmuir and Sips were very similar and
17 relatively high. High adsorption capacity is expected due to the relatively high surface area of
18 ALiCE. The Redlich-Peterson constant, β , was close to unity (0.965), demonstrating that the
19 isotherm can be reduced the Langmuir isotherm form [6]. Also, the values of $1/n$ were higher
20 than unity implying that the adsorption process is chemical. The R_L values are shown in Figure
21 5B (0.448 to 0.091) and suggest that the adsorption of MB onto ALiCE is a favourable one,
22 and at high C_0 values, the adsorption is nearly irreversible. Finally, the surface area of the
23 ALiCE was calculated using MB adsorption capacity (q_{\max}) and compared to that obtained by
24 the BET method (N_2 adsorption in gaseous phase). Assuming a complete adsorption of MB as
25 a monolayer on the ALiCE surface, the surface area can be calculated by:

1 Surface area (m^2/g) = $\frac{q_{\max} \times A_{MB} \times N_L \times 10^{-3}}{MW}$ (16)

2 where A_{MB} is the surface area taken by one molecule of MB = 130\AA^2 , N_L is the Avogadro's
3 number = 6.023×10^{23} molecule/mole and MW is the molecular weight of MB = 320g/mol.

4 The surface area of the ALiCE by MB adsorption was $88.69\text{m}^2/\text{g}$. This value is close to that
5 obtained by the BET method ($80.77\text{m}^2/\text{g}$). The slightly higher surface area accessed using the
6 MB adsorption method is attributed to the MB aggregation and the instrumental theory of a
7 cylindrical pore volumes which is not necessarily the case [34].

8 **3.7. Desorption studies**

9 The MB-loaded-ALiCE was eluted using HCl, deionized water and NaOH, and the amount of
10 MB desorbed (% desorption) was determined using the following relationship:

11 $Desorption \text{ (\%)} = \frac{C_{des}}{C_{ads}} \times 100$ (17)

12 where C_{des} is the concentration of dye in desorbed and C_{ads} (mg/dm^3) is the concentration at
13 adsorbed phases.

14 The amount of MB desorbed was relatively low with the maximum MB desorbed percentage
15 was 13.4% and it was obtained for strong acidic conditions (0.1M HCl). For higher pH values
16 (NaOH) and deionized water, the desorption was very low and limited to 4–7%. The low
17 desorption of MB by an acidic medium shows that the MB molecules were mainly adsorbed
18 onto the ALiCE through strong chemisorption mechanisms. The results indicate that the
19 regeneration of ALiCE by using acid or alkaline solutions is not feasible. However, the reduced
20 colour leachability from the dye-loaded ALiCE is a good property bearing in mind the disposal
21 in landfill or reuse for other purposes for instance: in polymeric composites or incorporation in
22 construction materials.

3.8. Adsorption mechanisms: FT-IR and SEM

The FT-IR spectra in Figure 6 shows structural changes in the ALiCE adsorbents after MB adsorption, confirmed by the changes of functional group bands due to the dye adsorption. The absorption peak around 3435 1/cm is due to stretching of phenolic and aliphatic –OH and –N H groups. The peaks at 2918 and 2850 1/cm correspond to C–H and –CH₂– stretching modes. The peak at 1626 1/cm is due to bending of –NH in primary amine group. Symmetric bending of –O–CH₃ is detected at 1458 1/cm. The peaks around 1200 1/cm are assigned to C–O–C stretching in α -O-4 and β -O-4 linkages of alkali lignin [35]. The peak at 671 1/cm is attributable to the out-of-plane bending of the O–H group. The changes in ALiCE surface characteristics i.e. change in all peak heights and shifts of functional group bands after MB loading indicate that groups for example hydroxyl and amine groups are involved in the adsorption process as expected. The SEM images demonstrated noteworthy changes in surface topography between the raw extruded lignin-chitosan blends, the activated extrudates and MB-loaded ALiCE. This deviation in the surface morphology is due to the activation process which has changed the quantities of available functionalities and their interactions. The development of chitosan agglomerates on the lignin surface before activation is obvious at the surface of the blends. This is due to the interactions between β -1,4-glycosidic linkage, amide and hydroxyl groups of chitosan, and ether, aromatic ring and hydroxyl groups of alkali lignin. After activation, the ALiCE surface was flattened with large, irregular intercellular spaces and well-defined edges. This indicates that the lignin-chitosan blended structure was rearranged during and after the activation. The SEM image of the MB-loaded-ALiCE showed that the edges and intercellular spaces of the microstructure disappeared after the MB adsorption and the structure is more relaxed with a paste like texture. The EDX chemical analysis of the ALiCE indicated that the unloaded ALiCE contained approx. 3.5% S and 5.7% Na. The EDX of the MB-loaded ALiCE showed the non-appearance of Na and that no apparent changes in elemental composition took place, signifying that ion-exchange is involved in the MB binding mechanisms. The structure

1 relaxation could be due to stripping of alkaline elements such as Na which is present in trace
2 quantities originating mainly from alkali lignin. The FT-IR and SEM analysis confirm that the
3 dye adsorption occurs possibly through electrostatic attractions/surface exchanges until the
4 functional sites are completely unavailable; subsequently, MB molecules diffuse into ALiCE
5 particles for more interactions possibly hydrophobic interactions and hydrogen bonding.

6 **4. Concluding remarks**

7 A new method involving extrusion and thermal activation was successfully employed in the
8 production of activated lignin-chitosan extruded (ALiCE) pellets. The ALiCE materials were
9 synthesized, structurally characterized, and used in selective cationic dye (methylene blue
10 (MB)) adsorption. The chemisorption dye adsorption mechanisms were revealed and it was
11 concluded that electrostatic attractions and chemical interactions were observed between amino
12 and hydroxyl groups of the ALiCE adsorbent and amine groups of the dye. Using the Langmuir
13 isotherm a maximum adsorption capacity of 36.25mg/g is calculated. The FTIR, electron
14 microscopy and desorption studies confirmed that strong chemical bonds occurred between the
15 MB molecules and the functional groups on the ALiCE.

16 **Acknowledgement**

17 The authors would like to thanks Mr James McClean from Queen's University Belfast for his
18 proofreading which has profoundly improved the quality of this article.
